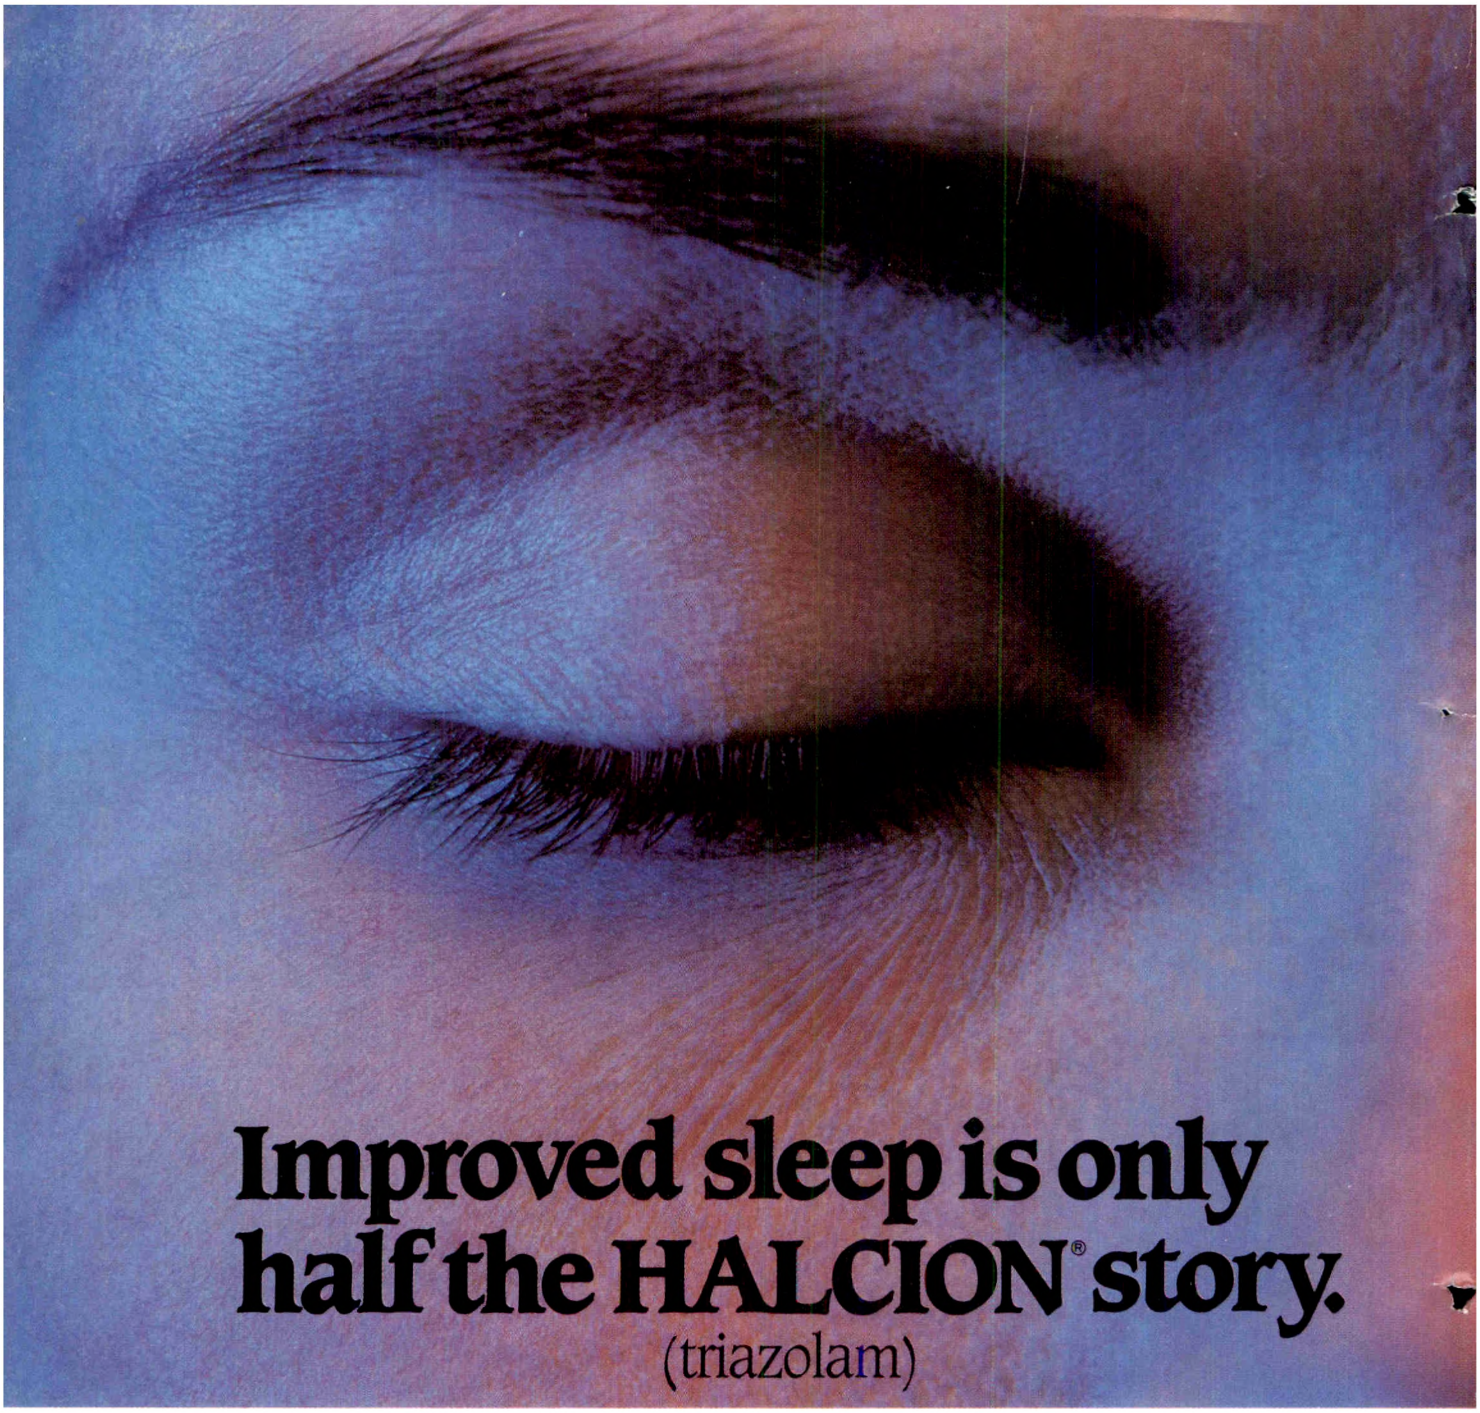
Is Sleep Deprivation Useful in the Treatment of Depression?
By Ellen Leibenluft and Thomas A. Wehr

Assessing Competency to Make a Will
By James E. Spar and Andrew S. Garb

Official Journal of the American Psychiatric Association



Improved sleep is only half the HALCION® story.
(triazolam)

## In depressed patients HALCION is effective when adjunctive insomnia therapy is required.

Disturbed sleep is not an uncommon problem in depressed patients, and although standard tricyclic antidepressants (TCAs) usually relieve insomnia, some depressed patients continue to experience its symptoms. The short-term use of HALCION to relieve insomnia refractory to treatment with TCAs has proven successful in two clinical evaluations.

### Effective, concomitant therapy.

HALCION was compared with placebo in a double-blind comparative study of 53 depressed outpatients who had been stabilized on a TCA for at least six weeks but who still suffered refractory insomnia. HALCION was shown to be more effective in relieving the symptoms of insomnia without making depressive symptoms worse.[1]

# Daytime alertness is the other half.

46

In another double-blind study comparing HALCION with placebo in 78 depressed outpatients receiving 50-300 mg of imipramine per day, HALCION was significantly more effective in improving most sleep parameters. In addition, there was no evidence that HALCION interfered with the efficacy of imipramine or aggravated the patients' depressive symptoms.[2]

These studies suggest that HALCION is effective adjunctive therapy for the relief of short-term insomnia in depressed patients.

Intentional overdosage of psychotropic medication is more common in depressed patients. Therefore, the least amount of medication that is feasible should be available at any one time.

The recommended dose for most adults is 0.25 mg before retiring. In geriatric and/or debilitated patients, therapy should be initiated at 0.125 mg.

0.125 & 0.25 MG TABLETS

## Halcion®
## triazolam Ⓘⓥ

**Helps meet both goals of insomnia therapy**

Please see adjacent page for prescribing information.

©1991 The Upjohn Company

## Halcion® Tablets (triazolam, ⓒⅣ Upjohn)

**INDICATIONS AND USAGE:** HALCION Tablets are indicated for the short-term treatment of insomnia (generally 7 to 10 days). Use for more than 2 to 3 weeks requires complete patient reevaluation (see WARNINGS).

Prescriptions for HALCION should be written for short-term use (7 to 10 days), and it should not be prescribed in quantities exceeding a 1-month supply.

**CONTRAINDICATIONS:** Patients with known hypersensitivity to this drug or other benzodiazepines.

HALCION is contraindicated in pregnant women due to potential fetal damage. Patients likely to become pregnant while receiving HALCION should be warned of the potential risk to the fetus.

**WARNINGS:** A decision to initiate symptomatic treatment of insomnia should only be made after the patient and sleep disturbance have been carefully evaluated. The failure of insomnia to remit after 7 to 10 days may indicate the presence of a primary psychiatric and/or medical illness.

Worsening insomnia or the emergence of new abnormalities of thinking or behavior may be the consequence of an unrecognized psychiatric or physical disorder. These have also been reported to occur in association with the use of HALCION.

Because some of the adverse effects of HALCION appear to be dose related (see PRECAUTIONS and DOSAGE AND ADMINISTRATION), it is important to use the smallest possible effective dose. Elderly patients are especially susceptible to dose-related adverse effects.

An increase in daytime anxiety has been reported for HALCION after as few as 10 days of continuous use. In some patients, this may be a manifestation of interdose withdrawal. If increased daytime anxiety occurs during treatment, discontinuation of treatment may be advisable.

A variety of abnormal thinking and behavior changes have been reported to occur in association with the use of benzodiazepine hypnotics, including HALCION. Some of these changes may be characterized by decreased inhibition, eg, aggressiveness and extroversion that seem excessive, similar to that seen with alcohol and other CNS depressants (eg, sedatives/hypnotics). Other kinds of behavior changes have also been reported, eg, bizarre behavior, agitation, hallucinations, and depersonalization. The worsening of depression, including suicidal thinking, has been reported in primarily depressed patients in association with the use of benzodiazepines.

The emergence of any new behavioral sign or symptom of concern requires careful and immediate evaluation.

Because of its depressant CNS effects, patients should be cautioned against engaging in hazardous occupations requiring complete mental alertness and also about the simultaneous ingestion of alcohol and other CNS-depressant drugs.

Anterograde amnesia and paradoxical reactions have been reported with HALCION and some other benzodiazepines. Data suggest that anterograde amnesia may occur at a higher rate with HALCION than with other benzodiazepine hypnotics.

**PRECAUTIONS:** *General:* In elderly and/or debilitated patients, treatment should be initiated at 0.125 mg to decrease the possibility of development of oversedation, dizziness, or impaired coordination. Some side effects, including drowsiness, dizziness, light-headedness, and amnesia, appear to be dose related.

Some evidence suggests that confusion, bizarre or abnormal behavior, agitation, and hallucinations may also be dose related, but evidence is inconclusive. Therapy should be initiated at the lowest effective dose. "Traveler's amnesia" has been reported when HALCION was taken to induce sleep while traveling. Caution should be exercised in patients with signs or symptoms of depression, which could be intensified by hypnotic drugs. Suicidal tendencies and intentional overdosage are more common in these patients. The usual precautions should be observed in patients with impaired renal or hepatic function, chronic pulmonary insufficiency, and sleep apnea. *Information for Patients* (see patient package insert for full information): Alert patients about (1) how, when, and how long to take HALCION, (2) not extending use of HALCION beyond 7 to 10 days without consulting physician, (3) the need to discuss with physician any unusual or disturbing thoughts or behavior that develop during treatment, (4) consumption of alcohol and drugs, (5) not taking HALCION when a full night's sleep and clearance from the body is not possible before they need to be active and functional, eg, an overnight flight of less than 7 to 8 hours, (6) not increasing prescribed dose, (7) not operating machinery or driving, (8) possible worsening of sleep after discontinuing HALCION, and (9) possible fetal abnormalities. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS-depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol, and other CNS depressants. Pharmacokinetic interactions of benzodiazepines with other drugs have been reported, eg, coadministration with either cimetidine or erythromycin approximately doubled the elimination half-life and plasma levels of triazolam. Therefore, increased clinical observation and consideration of dose reduction may be appropriate. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No evidence of carcinogenic potential. *Pregnancy:* Benzodiazepines may cause fetal damage if administered during pregnancy. The child born of a mother on benzodiazepines may have withdrawal symptoms and neonatal flaccidity postnatally. *Nursing Mothers:* Administration is not recommended.

*Pediatric Use:* Safety and efficacy in children below the age of 18 have not been established.

**ADVERSE REACTIONS:** During placebo-controlled clinical studies involving 1,003 patients treated with HALCION, the most troublesome side effects were extensions of the pharmacologic activity, eg, drowsiness (14% of patients). Other side effects reported by 4% to 10% of patients were headache, dizziness, nervousness, light-headedness, coordination disorder/ataxia, nausea, and vomiting.

Adverse events reported less frequently (ie, 0.5% to 0.9%) were euphoria, tachycardia, tiredness, confusional states/memory impairment, cramps/pain, depression, visual disturbances.

Rare (ie, less than 0.5%) adverse reactions included constipation, taste alterations, diarrhea, dry mouth, dermatitis/allergy, dreaming/nightmares, insomnia, paresthesia, tinnitus, dysesthesia, weakness, congestion, death from hepatic failure in a patient also receiving diuretic drugs.

The following adverse events have been reported in association with the use of HALCION and other benzodiazepines: amnestic symptoms, confusional states, dystonia, anorexia, fatigue, sedation, slurred speech, jaundice, pruritus, dysarthria, changes in libido, menstrual irregularities, incontinence, and urinary retention.

Other events reported include paradoxical reactions such as stimulation, mania, agitation, increased muscle spasticity, sleep disturbances, hallucinations, delusions, aggressiveness, falling, somnambulism, syncope, inappropriate behavior, and other adverse behavioral effects. Should these occur, the drug should be discontinued. Other reported events: chest pain, burning tongue/glossitis/stomatitis.

No laboratory changes were considered to be of physiologic significance.

When treatment is protracted, periodic blood counts, urinalysis, and blood chemistry analyses are advisable.

Minor changes in EEG patterns, of no known significance, have been observed in patients during therapy with HALCION.

**DRUG ABUSE AND DEPENDENCE:** *Controlled Substance:* HALCION Tablets are a Controlled Substance, Schedule IV. *Abuse, Dependence, and Withdrawal:* Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines given for as few as 1 to 2 weeks; and, in some patients, there may be withdrawal symptoms (daytime anxiety, agitation) between nightly doses. Abrupt discontinuation should be avoided, and gradual dosage tapering is recommended for any patient taking more than the lowest dose more than a few weeks. Patients with a history of seizures are at particular risk. Dependence-prone patients should be closely monitored. Repeat prescriptions should be limited to those under medical supervision.

**OVERDOSAGE:** Because of the potency of triazolam, overdosage may occur at 2 mg, four times the maximum recommended therapeutic dose (0.5 mg). Manifestations of overdosage include somnolence, confusion, impaired coordination, slurred speech, and ultimately, coma. Respiratory depression, apnea, seizures, and death have been reported. Respiration, pulse, and blood pressure should be monitored and supported by general measures when necessary. Immediate gastric lavage should be performed. Multiple agents may have been ingested.

**DOSAGE AND ADMINISTRATION:** The dosage of HALCION Tablets must be individualized and the lowest effective dose used. The recommended dose for most adults is 0.25 mg before retiring. A dose of 0.125 mg may be sufficient for some patients (eg, low body weight). Because the risk of several adverse reactions increases with dose size, a dose of 0.5 mg should be used only for exceptional patients who do not respond adequately to a trial of a lower dose. A dose of 0.5 mg should not be exceeded.

In geriatric and/or debilitated patients, the dosage range is 0.125 to 0.25 mg. Therapy should be initiated at 0.125 mg, and the 0.25-mg dose should be used only for exceptional patients who do not respond to a trial of the lower dose. A dose of 0.25 mg should not be exceeded in these patients.

**HOW SUPPLIED:** HALCION Tablets are available as 0.125-mg and 0.25-mg tablets.

Store at controlled room temperature 15°-30°C (59°-86°F).

Caution: Federal law prohibits dispensing without prescription. B-8-S

# Psychiatrist
## Traumatic Brain Injury

Exciting clinical/academic opportunity for a psychiatrist interested in delivering care to adult patients with traumatic brain injury and associated psychiatric or behavioral disturbances. Allegheny Neuropsychiatric Institute is a 94-bed hospital specializing in psychiatric treatment of patients with concomitant neurological disorders. The institute is a major clinical and teaching site within the rapidly expanding Department of Psychiatry at the Medical College of Pennsylvania, Allegheny Campus.

This clinical/academic staff position includes inpatient and outpatient clinical responsibilities, the opportunity to work with an outstanding multi-disciplinary staff, abundant teaching and research opportunities, full faculty appointment at the Medical College of Pennsylvania and competitive salary and flexible benefit packages. Candidates must be board certified or board eligible in adult psychiatry. Please send curriculum vitae or call or write:

DISTA

FL-4931-T-149317 ©1991, DISTA PRODUCTS COMPANY

# Prozac®

## fluoxetine hydrochloride

**Brief Summary. Consult the package insert for complete prescribing information.**

**Indication:** For the treatment of depression.

**Contraindications:** Known hypersensitivity to Prozac.

*Monoamine Oxidase Inhibitors* — There have been reports of serious, sometimes fatal, reactions in patients receiving fluoxetine in combination with an MAOI and in patients who have recently discontinued fluoxetine and are then started on an MAOI. Some cases presented with features resembling neuroleptic malignant syndrome.

Wait at least 14 days between discontinuing an MAOI and starting therapy with Prozac. Because of the long half-lives of fluoxetine and its active metabolite, wait at least 5 weeks between discontinuing Prozac and starting therapy with an MAOI. Prozac should not be used concomitantly with MAOIs.

**Warnings:** *Rash and Possibly Allergic Events* — Approximately 4% of 5,600 fluoxetine patients developed a rash and/or urticaria in premarketing testing. Almost a third of these discontinued therapy because of rash and/or associated systemic signs or symptoms. Reported in association with rash were fever, leukocytosis, arthralgias, edema, carpal tunnel syndrome, respiratory distress, lymphadenopathy, proteinuria, and mild transaminase elevation. Most patients improved promptly upon discontinuation of fluoxetine and/or adjunctive treatment with antihistamines or steroids, and all were reported to recover completely.

Of 2 patients who developed a serious cutaneous systemic illness during premarketing clinical trials, 1 was considered to have a leukocytoclastic vasculitis, and the other, a severe desquamating syndrome considered variously to be a vasculitis or erythema multiforme. Other patients have had systemic syndromes suggestive of serum sickness.

Since the introduction of Prozac, systemic events possibly related to vasculitis have developed in patients with rash. Although these events are rare, they may be serious, involving the lung, kidney, or liver. Death has been reported to occur in association with these systemic events.

Anaphylactoid events, including bronchospasm, angioedema, and urticaria alone and in combination, have been reported.

Pulmonary events, including inflammatory processes of varying histopathology and/or fibrosis, have been reported rarely. These events have occurred with dyspnea as the only preceding symptom.

Whether these systemic events and rash have a common underlying cause or represent immunologic responses is not known. Upon the appearance of rash or of other possibly allergic phenomena for which an alternative etiology cannot be identified, Prozac should be discontinued.

**Precautions:** *General* — Anxiety, Nervousness, and Insomnia — Reported by 10% to 15% of patients, 5% of whom discontinued fluoxetine.

Altered Appetite and Weight — Significant weight loss, especially in underweight patients, may be an undesirable result of treatment.

Approximately 9% of fluoxetine patients experienced anorexia in controlled clinical trials, an incidence approximately sixfold that seen with placebo. A weight loss >5% of body weight occurred in 13% of fluoxetine patients compared with 4% in those on placebo and 3% in those on tricyclics. However, only rarely did fluoxetine patients discontinue treatment because of weight loss.

Activation of Mania/Hypomania — Hypomania or mania occurred in approximately 1% of fluoxetine patients in premarketing testing.

Seizures — Twelve of 6,000 patients (0.2%) experienced convulsions (or, possibly, seizures). Prozac should be introduced with care in patients with a history of seizures.

Suicide — Close supervision of high-risk patients should accompany initial therapy. Prescriptions of Prozac should be written for the smallest quantity of capsules consistent with good patient management to reduce the risk of overdose.

The Long Elimination Half-Lives of Fluoxetine and Its Metabolites — Because of the long elimination half-lives of the parent drug (2 to 3 days) and its major active metabolite (7 to 9 days), changes in dose will not be fully reflected in plasma for several weeks, affecting both strategies for titration to final dose and withdrawal from treatment.

Use in Patients with Concomitant Illness — Caution is advisable in patients with diseases or conditions that could affect metabolism or hemodynamic responses.

Fluoxetine has **not** been evaluated or used to any appreciable extent in patients with a recent history of myocardial infarction or unstable heart disease. ECGs of 312 patients who received Prozac in double-blind trials were retrospectively evaluated; no conduction abnormalities that resulted in heart block were observed. The mean heart rate was reduced by approximately 3 beats/min.

In subjects with cirrhosis, the clearances of fluoxetine and its active metabolite were decreased. A lower or less frequent dose should be used in patients with cirrhosis.

Fluoxetine should be used with caution in patients with severe renal impairment.

In patients with diabetes, Prozac may alter glycemic control. Hypoglycemia has occurred during therapy with Prozac, and hyperglycemia has developed following discontinuation. Insulin and/or oral hypoglycemic dosage may need to be adjusted when fluoxetine therapy is instituted or discontinued.

Interference with Cognitive and Motor Performance — Any psychoactive drug may impair judgment, thinking, or motor skills, and patients should be cautioned about operating hazardous machinery, including automobiles, until they are reasonably certain that the drug does not affect them adversely.

*Information for Patients* — Physicians should advise their patients to notify them if they:

- are taking or plan to take any prescription or over-the-counter drugs or alcohol
- become pregnant or intend to become pregnant during therapy
- are breast feeding an infant
- develop a rash or hives

*Drug Interactions* — Tryptophan — Five patients receiving tryptophan experienced adverse reactions, including agitation, restlessness, and gastrointestinal distress.

Monoamine Oxidase Inhibitors — *See* Contraindications.

Other Antidepressants — There have been greater than twofold increases of previously stable plasma levels of other antidepressants when Prozac has been administered in combination with these agents.

Lithium — There have been reports of both increased and decreased lithium levels and lithium toxicity. Lithium levels should be monitored.

Diazepam Clearance — The half-life of diazepam may be prolonged in some patients.

Drugs Tightly Bound to Plasma Proteins — Because fluoxetine is tightly bound to plasma protein, the concurrent administration of fluoxetine and another tightly bound drug may cause a shift in plasma concentrations potentially resulting in an adverse effect. Adverse effects may also result from displacement of protein-bound fluoxetine by other tightly bound drugs.

CNS-Active Drugs — Caution is advised if the concomitant administration of Prozac and such drugs is required.

Electroconvulsive Therapy — There have been rare reports of prolonged seizures in patients on fluoxetine receiving ECT treatment.

*Carcinogenesis, Mutagenesis, Impairment of Fertility* — There is no evidence of carcinogenicity, mutagenicity, or impairment of fertility with Prozac.

The dietary administration of fluoxetine to rats and mice for 2 years at doses approximately 7.5 and 9.0 times the maximum human dose (80 mg) respectively revealed no evidence of carcinogenicity.

Fluoxetine and norfluoxetine have been shown to have no genotoxic effects based on the following assays: bacterial mutation assay, DNA repair assay in cultured rat hepatocytes, mouse lymphoma assay, and in vivo sister chromatid exchange assay in Chinese hamster bone marrow cells.

Two fertility studies in rats at doses approximately 5 and 9 times the maximum human dose (80 mg) respectively revealed no adverse effects on fertility. A slight decrease in neonatal survival was noted, probably associated with depressed maternal food consumption and suppressed weight gain.

*Pregnancy* — Teratogenic Effects — Pregnancy Category B — Reproduction studies in rats and rabbits at doses 9 and 11 times the maximum human dose (80 mg) respectively revealed no evidence of harm to the fetus. Although there have been no adequate and well-controlled studies in pregnant women, this drug should be used during pregnancy only if clearly needed.

*Labor and Delivery* — The effect of Prozac on labor and delivery in humans is unknown.

*Nursing Mothers* — Because Prozac is known to be excreted in human milk, caution should be exercised when Prozac is administered to a nursing woman.

*Usage in Children* — Safety and effectiveness in children have not been established.

*Usage in the Elderly* — In clinical studies of several hundred elderly patients, no unusual adverse age-related phenomena were identified. However, these data are insufficient to rule out possible age-related differences during chronic use, particularly in elderly patients with concomitant systemic illnesses or those receiving concomitant drugs.

*Hyponatremia* — Hyponatremia (some cases with serum Na <110 mmol/L) has been reported, which appeared to be reversible on drug discontinuation. Some cases were possibly due to SIADH, and the majority have been in older patients and those taking diuretics or otherwise volume depleted.

*Platelet Function* — There have been rare reports of altered platelet function and/or abnormal results from laboratory studies in patients taking fluoxetine. While there have been reports of abnormal bleeding in several patients taking fluoxetine, it is unclear whether fluoxetine had a causative role.

**Adverse Reactions:** *Commonly Observed* — Nervous system complaints, including anxiety, nervousness, and insomnia; drowsiness and fatigue or asthenia; tremor; sweating; gastrointestinal complaints, including anorexia, nausea, and diarrhea; and dizziness or lightheadedness.

*Associated With Discontinuation of Treatment* — Fifteen percent of 4,000 clinical trial patients discontinued fluoxetine due to an adverse event. The more common events included: psychiatric (5.3%), primarily nervousness, anxiety, and insomnia; digestive (3.0%), primarily nausea; nervous system (1.6%), primarily dizziness; body as a whole (1.5%), primarily asthenia and headache; and skin (1.4%), primarily rash and pruritus.

*Incidence in Controlled Clinical Trials* — The accompanying table enumerates adverse events that occurred at a frequency of ≥ 1% in controlled trials.

TREATMENT-EMERGENT ADVERSE EXPERIENCE INCIDENCE
IN PLACEBO-CONTROLLED CLINICAL TRIALS

| | Percentage of Patients Reporting Event | | | Percentage of Patients Reporting Event | |
|---|---|---|---|---|---|
| Body System/ Adverse Event* | Prozac (N = 1,730) | Placebo (N = 799) | Body System/ Adverse Event* | Prozac (N=1,730) | Placebo (N=799) |

*Events reported by ≥1% of fluoxetine patients are included.
— Incidence <1%

*Other Events Observed During Premarketing Evaluation in 5,600 Fluoxetine Patients* — Frequent adverse events are defined as those occurring on 1 or more occasions in at least 1/100 patients; infrequent adverse events are those occurring in 1/100 to 1/1,000 patients; rare events are those occurring in less than 1/1,000 patients.

Body as a Whole — *Frequent:* chills; *Infrequent:* chills and fever, cyst, face edema, hangover effect, jaw pain, malaise, neck pain, neck rigidity, and pelvic pain; *Rare:* abdomen enlarged, cellulitis, hydrocephalus, hypothermia, LE syndrome, moniliasis, and serum sickness.

Cardiovascular System — *Infrequent:* angina pectoris, arrhythmia, hemorrhage, hypertension, hypotension, migraine, postural hypotension, syncope, and tachycardia; *Rare:* AV block first-degree, bradycardia, bundle branch block, cerebral ischemia, myocardial infarct, thrombophlebitis, vascular headache, and ventricular arrhythmia.

Digestive System — *Frequent:* increased appetite; *Infrequent:* aphthous stomatitis, dysphagia, eructation, esophagitis, gastritis, gingivitis, glossitis, liver function tests abnormal, melena, stomatitis, thirst; *Rare:* bloody diarrhea, cholecystitis, cholelithiasis, colitis, duodenal ulcer, enteritis, fecal incontinence, hematemesis, hepatitis, hepatomegaly, hyperchlorhydria, increased salivation, jaundice, liver tenderness, mouth ulceration, salivary gland enlargement, stomach ulcer, tongue discoloration, and tongue edema.

Endocrine System — *Infrequent:* hypothyroidism; *Rare:* goiter and hyperthyroidism.

Hemic and Lymphatic System — *Infrequent:* anemia and lymphadenopathy; *Rare:* bleeding time increased, blood dyscrasia, leukopenia, lymphocytosis, petechia, purpura, sedimentation rate increased, and thrombocythemia.

Metabolic and Nutritional — *Frequent:* weight loss; *Infrequent:* generalized edema, hypoglycemia, peripheral edema, and weight gain; *Rare:* dehydration, gout, hypercholesteremia, hyperglycemia, hyperlipemia, hypoglycemic reaction, hypokalemia, hyponatremia, and iron deficiency anemia.

Musculoskeletal System — *Infrequent:* arthritis, bone pain, bursitis, tenosynovitis, and twitching; *Rare:* bone necrosis, chondrodystrophy, muscle hemorrhage, myositis, osteoporosis, pathological fracture, and rheumatoid arthritis.

Nervous System — *Frequent:* abnormal dreams and agitation; *Infrequent:* abnormal gait, acute brain syndrome, akathisia, amnesia, apathy, ataxia, buccoglossal syndrome, CNS stimulation, convulsion, delusions, depersonalization, emotional lability, euphoria, hallucinations, hostility, hyperkinesia, hypesthesia, incoordination, libido increased, manic reaction, neuralgia, neuropathy, paranoid reaction, psychosis, and vertigo; *Rare:* abnormal electroencephalogram, antisocial reaction, chronic brain syndrome, circumoral paresthesia, CNS depression, coma, dysarthria, dystonia, extrapyramidal syndrome, hypertonia, hysteria, myoclonus, nystagmus, paralysis, reflexes decreased, stupor, and torticollis.

Respiratory System — *Frequent:* bronchitis, rhinitis, and yawn; *Infrequent:* asthma, epistaxis, hiccup, hyperventilation, and pneumonia; *Rare:* apnea, hemoptysis, hypoxia, larynx edema, lung edema, lung fibrosis/alveolitis, and pleural effusion.

Skin and Appendages — *Infrequent:* acne, alopecia, contact dermatitis, dry skin, herpes simplex, maculopapular rash, and urticaria; *Rare:* eczema, erythema multiforme, fungal dermatitis, herpes zoster, hirsutism, psoriasis, purpuric rash, pustular rash, seborrhea, skin discoloration, skin hypertrophy, subcutaneous nodule, and vesiculobullous rash.

Special Senses — *Infrequent:* amblyopia, conjunctivitis, ear pain, eye pain, mydriasis, photophobia, and tinnitus; *Rare:* blepharitis, cataract, corneal lesion, deafness, diplopia, eye hemorrhage, glaucoma, iritis, ptosis, strabismus, and taste loss.

Urogenital System — *Infrequent:* abnormal ejaculation, amenorrhea, breast pain, cystitis, dysuria, fibrocystic breast, impotence, leukorrhea, menopause, menorrhagia, ovarian disorder, urinary incontinence, urinary retention, urinary urgency, urination impaired, and vaginitis; *Rare:* abortion, albuminuria, breast enlargement, dyspareunia, epididymitis, female lactation, hematuria, hypomenorrhea, kidney calculus, metrorrhagia, orchitis, polyuria, pyelonephritis, pyuria, salpingitis, urethral pain, urethritis, urinary tract disorder, urolithiasis, uterine hemorrhage, uterine spasm, and vaginal hemorrhage.

*Postintroduction Reports* — Voluntary reports of adverse events temporally associated with Prozac that have been received since market introduction and which may have no causal relationship with the drug include the following: aplastic anemia, cerebral vascular accident, confusion, dyskinesia (including, for example, a case of buccal-lingual-masticatory syndrome with involuntary tongue protrusion reported to develop in a 77-year old female after 5 weeks of fluoxetine therapy and which completely resolved over the next few months following drug discontinuation), ecchymoses, eosinophilic pneumonia, gastrointestinal hemorrhage, hyperprolactinemia, movement disorders developing in patients with risk factors including drugs associated with such events and worsening of preexisting movement disorders, neuroleptic malignant syndrome-like events, pancreatitis, pancytopenia, suicidal ideation, thrombocytopenia, thrombocytopenic purpura, vaginal bleeding after drug withdrawal, and violent behaviors.

**Overdosage**: *Human Experience* — As of December 1987, there were 2 deaths among approximately 38 reports of acute overdose with fluoxetine, either alone or in combination with other drugs and/or alcohol. One death involved a combined overdose with approximately 1,800 mg of fluoxetine and an undetermined amount of maprotiline. A second death involved fluoxetine, codeine, and temazepam.

One other patient who reportedly took 3,000 mg of fluoxetine experienced 2 grand mal seizures that remitted spontaneously without specific anticonvulsant treatment. The actual amount of drug absorbed may have been less due to vomiting.

Nausea and vomiting were prominent in overdoses involving higher fluoxetine doses. Other prominent symptoms of overdose included agitation, restlessness, hypomania, and other signs of CNS excitation. Except for the 2 deaths noted above, all other overdose cases recovered without residua.

A single death attributed to overdose of fluoxetine alone has been reported.

# Anafranil®
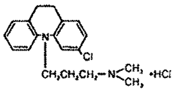
## clomipramine hydrochloride
## Capsules

## Prescribing Information

### DESCRIPTION
Anafranil, clomipramine hydrochloride, is an antiobsessional drug that belongs to the class (dibenzazepine) of pharmacologic agents known as tricyclic antidepressants. Anafranil is available as capsules of 25, 50, and 75 mg for oral administration.

Clomipramine hydrochloride is 3-chloro-5-[3-(dimethylamino)propyl]-10,11-dihydro-5H-dibenz[b,f]azepine monohydrochloride, and its structural formula is:



Clomipramine hydrochloride is a white to off-white crystalline powder. It is freely soluble in water, in methanol, and in methylene chloride, and insoluble in ethyl ether and in hexane. Its molecular weight is 351.3.

*Inactive Ingredients*. D&C Red No. 33 (25-mg capsules only), D&C Yellow No. 10, FD&C Blue No. 1 (50-mg capsules only), FD&C Yellow No. 6, gelatin, magnesium stearate, methylparaben, propylparaben, silicon dioxide, sodium lauryl sulfate, starch, and titanium dioxide.

### CLINICAL PHARMACOLOGY
#### Pharmacodynamics
Clomipramine (CMI) is presumed to influence obsessive and compulsive behaviors through its effects on serotonergic neuronal transmission. The actual neurochemical mechanism is unknown, but CMI's capacity to inhibit the reuptake of serotonin (5-HT) is thought to be important.

#### Pharmacokinetics
***Absorption/Bioavailability:*** CMI from Anafranil capsules is as bioavailable as CMI from a solution. The bioavailability of CMI from capsules is not significantly affected by food.

In a dose proportionality study involving multiple CMI doses, steady-state plasma concentrations ($C_{ss}$) and area-under-plasma-concentration-time curves (AUC) of CMI and CMI's major active metabolite, desmethylclomipramine (DMI), were not proportional to dose over the ranges evaluated, i.e., between 25-100 mg/day and between 25-150 mg/day, although $C_{ss}$ and AUC are approximately linearly related to dose between 100-150 mg/day. The relationship between dose and CMI/DMI concentrations at higher daily doses has not been systematically assessed, but if there is significant dose dependency at doses above 150 mg/day, there is the potential for dramatically higher $C_{ss}$ and AUC even for patients dosed within the recommended range. This may pose a potential risk to some patients (see WARNINGS and PRECAUTIONS, Drug Interactions).

After a single 50-mg oral dose, maximum plasma concentrations of CMI occur within 2-6 hours (mean, 4.7 hr) and range from 56 ng/ml to 154 ng/ml (mean, 92 ng/ml). After multiple daily doses of 150 mg of Anafranil, steady-state maximum plasma concentrations range from 94 ng/ml to 339 ng/ml (mean, 218 ng/ml) for CMI and from 134 ng/ml to 532 ng/ml (mean, 274 ng/ml) for DMI. No pharmacokinetic information is available for doses ranging from 150 mg/day to 250 mg/day, the maximum recommended daily dose.

***Distribution:*** CMI distributes into cerebrospinal fluid (CSF) and brain and into breast milk. DMI also distributes into CSF, with a mean CSF/plasma ratio of 2.6. The protein binding of CMI is approximately 97%, principally to albumin, and is independent of CMI concentration. The interaction between CMI and other highly protein-bound drugs has not been fully evaluated, but may be important (see PRECAUTIONS, Drug Interactions).

***Metabolism:*** CMI is extensively biotransformed to DMI and other metabolites and their glucuronide conjugates. DMI is pharmacologically active, but its effects on OCD behaviors are unknown. These metabolites are excreted in urine and feces, following biliary elimination. After a 25-mg radiolabeled dose of CMI in two subjects, 60% and 51%, respectively, of the dose were recovered in the urine and 32% and 24%, respectively, in feces. In the same study, the combined urinary recoveries of CMI and DMI were only about 0.8-1.3% of the dose administered. CMI does not induce drug-metabolizing enzymes, as measured by antipyrine half-life.

***Elimination:*** Evidence that the $C_{ss}$ and AUC for CMI and DMI may increase disproportionately with increasing oral doses suggests that the metabolism of CMI and DMI may be capacity limited. This fact must be considered in assessing the estimates of the pharmacokinetic parameters presented below, as these were obtained in individuals exposed to doses of 150 mg. If the pharmacokinetics of CMI and DMI are nonlinear at doses above 150 mg, their elimination half-lives may be considerably lengthened at doses near the upper end of the recommended dosing range (i.e., 200 mg/day to 250 mg/day). Consequently, CMI and DMI may accumulate, and this accumulation may increase the incidence of any dose- or plasma-concentration-dependent adverse reactions, in particular seizures (see WARNINGS).

After a 150-mg dose, the half-life of CMI ranges from 19 hours to 37 hours (mean, 32 hr) and that of DMI ranges from 54 hours to 77 hours (mean, 69 hr). Steady-state levels after multiple dosing are typically reached within 7-14 days for CMI. Plasma concentrations of the metabolite exceed the parent drug on multiple dosing. After multiple dosing with 150 mg/day, the accumulation factor for CMI is approximately 2.5 and for DMI is 4.6. Importantly, it may take two weeks or longer to achieve this extent of accumulation at constant dosing because of the relatively long elimination half-lives of CMI and DMI (see DOSAGE AND ADMINISTRATION). The effects of hepatic and renal impairment on the disposition of Anafranil have not been determined.

*Interactions:* Coadministration of haloperidol with CMI increases plasma concentrations of CMI. Coadministration of CMI with phenobarbital increases plasma concentrations of phenobarbital (see PRECAUTIONS, Drug Interactions). Younger subjects (18-40 years of age) tolerated CMI better and had significantly lower steady-state plasma concentrations, compared with subjects over 65 years of age. Children under 15 years of age had significantly lower plasma concentration/dose ratios, compared with adults. Plasma concentrations of CMI were significantly lower in smokers than in nonsmokers.

### INDICATIONS AND USAGE
Anafranil is indicated for the treatment of obsessions and compulsions in patients with Obsessive-Compulsive Disorder (OCD). The obsessions or compulsions must cause marked distress, be time-consuming, or significantly interfere with social or occupational functioning, in order to meet the DSM-III-R (circa 1989) diagnosis of OCD.

Obsessions are recurrent, persistent ideas, thoughts, images, or impulses that are ego-dystonic. Compulsions are repetitive, purposeful, and intentional behaviors performed in response to an obsession or in a stereotyped fashion, and are recognized by the person as excessive or unreasonable.

The effectiveness of Anafranil for the treatment of OCD was demonstrated in multicenter, placebo-controlled, parallel-group studies, including two 10-week studies in adults and one 8-week study in children and adolescents 10-17 years of age. Patients in all studies had moderate-to-severe OCD (DSM-III), with mean baseline ratings on the Yale-Brown Obsessive Compulsive Scale (YBOCS) ranging from 26 to 28 and a mean baseline rating of 10 on the NIMH Clinical Global Obsessive Compulsive Scale (NIMH-OC). Patients taking CMI experienced a mean reduction of approximately 10 on the YBOCS, representing an average improvement on this scale of 35% to 42% among adults and 37% among children and adolescents. CMI treated patients experienced a 3.5 unit decrement on the NIMH-OC. Patients on placebo showed no important clinical response on either scale. The maximum dose was 250 mg/day for most adults and 3 mg/kg/day (up to 200 mg) for all children and adolescents.

The effectiveness of Anafranil for long-term use (i.e., for more than 10 weeks) has not been systematically evaluated in placebo-controlled trials. The physician who elects to use Anafranil for extended periods should periodically reevaluate the long-term usefulness of the drug for the individual patient (see DOSAGE AND ADMINISTRATION).

### CONTRAINDICATIONS
Anafranil is contraindicated in patients with a history of hypersensitivity to Anafranil or other tricyclic antidepressants.

Anafranil should not be given in combination, or within 14 days before or after treatment, with a monoamine oxidase (MAO) inhibitor. Hyperpyretic crisis, seizures, coma, and death have been reported in patients receiving such combinations.

Anafranil is contraindicated during the acute recovery period after a myocardial infarction.

### WARNINGS
#### Seizures
During premarket evaluation, seizure was identified as the most significant risk of Anafranil use.

The observed cumulative incidence of seizures among patients exposed to Anafranil at doses up to 300 mg/day was 0.64% at 90 days, 1.12% at 180 days, and 1.45% at 365 days. The cumulative rates correct the crude rate of 0.7% (25 of 3519 patients) for the variable duration of exposure in clinical trials.

Although dose appears to be a predictor of seizure, there is a confounding of dose and duration of exposure, making it difficult to assess independently the effect of either factor alone. The ability to predict the occurrence of seizures in subjects exposed to doses of CMI greater than 250 mg is limited, given that the plasma concentration of CMI may be dose-dependent and may vary among subjects given the same dose. Nevertheless, prescribers are advised to limit the daily dose to a maximum of 250 mg in adults and 3 mg/kg (or 200 mg) in children and adolescents (see DOSAGE AND ADMINISTRATION).

Caution should be used in administering Anafranil to patients with a history of seizures or other predisposing factors, e.g., brain damage of varying etiology, alcoholism, and concomitant use with other drugs that lower the seizure threshold.

Rare reports of fatalities in association with seizures have been reported by foreign post-marketing surveillance, but not in U.S. clinical trials. In some of these cases, Anafranil had been administered with other epileptogenic agents; in others, the patients involved had possibly predisposing medical conditions. Thus a causal association between Anafranil treatment and these fatalities has not been established.

Physicians should discuss with patients the risk of taking Anafranil while engaging in activities in which sudden loss of consciousness could result in serious injury to the patient or others, e.g., the operation of complex machinery, driving, swimming, climbing.

### PRECAUTIONS
#### General
***Suicide:*** Since depression is a commonly associated feature of OCD, the risk of suicide must be considered. Prescriptions for Anafranil should be written for the smallest quantity of capsules consistent with good patient management, in order to reduce the risk of overdose.

***Cardiovascular Effects:*** Modest orthostatic decreases in blood pressure and modest tachycardia were each seen in approximately 20% of patients taking Anafranil in clinical trials; but patients were frequently asymptomatic. Among approximately 1400 patients treated with CMI in the premarketing experience who had ECGs, 1.5% developed abnormalities during treatment, compared with 3.1% of patients receiving active control drugs and 0.7% of patients receiving placebo. The most common ECG changes were PVCs, ST-T wave changes, and intraventricular conduction abnormalities. These changes were rarely associated with significant clinical symptoms. Nevertheless, caution is necessary in treating patients with known cardiovascular disease, and gradual dose titration is recommended.

***Psychosis, Confusion, And Other Neuropsychiatric Phenomena:*** Patients treated with Anafranil have been reported to show a variety of neuropsychiatric signs and symptoms including delusions, hallucinations, psychotic episodes, confusion, and paranoia. Because of the uncontrolled nature of many of the studies, it is impossible to provide a precise estimate of the extent of risk imposed by treatment with Anafranil. As with tricyclic antidepressants to which it is closely related, Anafranil may precipitate an acute psychotic episode in patients with unrecognized schizophrenia.

***Mania/Hypomania:*** During premarketing testing of Anafranil in patients with affective disorder, hypomania or mania was precipitated in several patients. Activation of mania or hypomania has also been reported in a small proportion of patients with affective disorder treated with marketed tricyclic antidepressants, which are closely related to Anafranil.

***Hepatic Changes:*** During premarketing testing, Anafranil was occasionally associated with elevations in SGOT and SGPT (pooled incidence of approximately 1% and 3%, respectively) of potential clinical importance (i.e., values greater than 3 times the upper limit of normal). In the vast majority of instances these enzyme increases were not associated with other clinical findings suggestive of hepatic injury; moreover, none were jaundiced. Rare reports of more severe liver injury, some fatal, have been recorded in foreign post-marketing experience. Caution is indicated in treating patients with known liver disease, and periodic monitoring of hepatic enzyme levels is recommended in such patients.

***Hematologic Changes:*** Although no instances of severe hematologic toxicity were seen in the premarketing experience with Anafranil, there have been post-marketing reports of leukopenia, agranulocytosis, thrombocytopenia, anemia, and pancytopenia in association with Anafranil use. As is the case with tricyclic antidepressants to which Anafranil is closely related, leukocyte and differential blood counts should be obtained in patients who develop fever and sore throat during treatment with Anafranil.

***Central Nervous System:*** More than 30 cases of hyperthermia have been recorded by nondomestic post-marketing surveillance systems. Most cases occurred when Anafranil was used in combination with other drugs when Anafranil and a neuroleptic were used concomitantly, the cases were sometimes considered to be examples of a neuroleptic malignant syndrome.

***Sexual Dysfunction:*** The rate of sexual dysfunction in male patients with OCD who were treated with Anafranil in the premarketing experience was markedly increased compared with placebo controls (i.e., 42% experienced ejaculatory failure and 20% experienced impotence, compared with 2.0% and 2.6%, respectively, in the placebo group). Approximately 85% of males with sexual dysfunction chose to continue treatment.

***Weight Changes:*** In controlled studies of OCD, weight gain was reported in 18% of patients receiving Anafranil, compared with 1% of patients receiving placebo. In these studies, 28% of patients receiving Anafranil had a weight gain of at least 7% of their initial body weight, compared with 4% of patients receiving placebo. Several patients had weight gains in excess of 25% of their initial body weight. Conversely, 5% of patients receiving Anafranil and 1% receiving placebo had weight losses of at least 7% of their initial body weight.

***Electroconvulsive Therapy:*** As with closely related tricyclic antidepressants, concurrent administration of Anafranil with electroconvulsive therapy may increase the risks; such treatment should be limited to those patients for whom it is essential, since there is limited clinical experience.

***Surgery:*** Prior to elective surgery with general anesthetics, therapy with Anafranil should be discontinued for as long as is clinically feasible, and the anesthetist should be advised.

***Use in Concomitant Illness:*** As with closely related tricyclic antidepressants, Anafranil should be used with caution in the following:

1. Hyperthyroid patients or patients receiving thyroid medication, because of the possibility of cardiac toxicity;
2. Patients with increased intraocular pressure, a history of narrow-angle glaucoma, or urinary retention, because of the anticholinergic properties of the drug;
3. Patients with tumors of the adrenal medulla (e.g., pheochromocytoma, neuroblastoma) in whom the drug may provoke hypertensive crises;
4. Patients with significantly impaired renal function.

***Withdrawal Symptoms:*** A variety of withdrawal symptoms have been reported in association with abrupt discontinuation of Anafranil, including dizziness, nausea, vomiting, headache, malaise, sleep disturbance, hyperthermia, and irritability. In addition, such patients may experience a worsening of psychiatric status. While the withdrawal effects of Anafranil have not been systematically evaluated in controlled trials, they are well known with closely related tricyclic antidepressants, and it is recommended that the dosage be tapered gradually and the patient monitored carefully during discontinuation (see DRUG ABUSE AND DEPENDENCE).

#### Information for Patients
Physicians are advised to discuss the following issues with patients for whom they prescribe Anafranil:

1. The risk of seizure (see WARNINGS);
2. The relatively high incidence of sexual dysfunction among males (see Sexual Dysfunction);
3. Since Anafranil may impair the mental and/or physical abilities required for the performance of complex tasks, and since Anafranil is associated with a risk of seizures, patients should be cautioned about the performance of complex and hazardous tasks (see WARNINGS);
4. Patients should be cautioned about using alcohol, barbiturates, or other CNS depressants concurrently, since Anafranil may exaggerate their response to these drugs;
5. Patients should notify their physician if they become pregnant or intend to become pregnant during therapy;
6. Patients should notify their physician if they are breast-feeding.

#### Drug Interactions
The risks of using Anafranil in combination with other drugs have not been systematically evaluated. Given the primary CNS effects of Anafranil, caution is advised in using it concomitantly with other CNS-active drugs (see Information for Patients). Anafranil should *not* be used with MAO inhibitors (see CONTRAINDICATIONS).

Close supervision and careful adjustment of dosage are required when Anafranil is administered with anticholinergic or sympathomimetic drugs.

Several tricyclic antidepressants have been reported to block the pharmacologic effects of guanethidine, clonidine, or similar agents, and such an effect may be anticipated with CMI because of its structural similarity to other tricyclic antidepressants.

The plasma concentration of CMI has been reported to be increased by the concomitant administration of haloperidol; plasma levels of several closely related tricyclic antidepressants have been reported to be increased by the concomitant administration of either methylphenidate, cimetidine, or fluoxetine and such an effect may be anticipated with CMI as well. Administration of CMI has been reported to increase the plasma levels of phenobarbital, if given concomitantly (see CLINICAL PHARMACOLOGY, Interactions).

Because Anafranil is highly bound to serum protein, the administration of Anafranil to patients taking other drugs that are highly bound to protein (e.g., warfarin, digoxin) may cause an increase in plasma concentrations of these drugs, potentially resulting in adverse effects. Conversely, adverse effects may result from displacement of protein-bound Anafranil by other highly bound drugs (see CLINICAL PHARMACOLOGY, Distribution).

#### Carcinogenesis, Mutagenesis, Impairment of Fertility
In a 2-year bioassay, no clear evidence of carcinogenicity was found in rats given doses 20 times the maximum daily human dose. Three out of 235 treated rats had a rare tumor (hemangioendothelioma); it is unknown if these neoplasms are compound related.

In reproduction studies, no effects on fertility were found in rats given doses approximately 5 times the maximum daily human dose.

#### Pregnancy Category C
No teratogenic effects were observed in studies performed in rats and mice at doses up to 20 times the maximum daily human dose. Slight nonspecific fetotoxic effects were seen in the offspring of pregnant mice given doses 10 times the maximum daily human dose. Slight nonspecific embryotoxicity was observed in rats given doses 5-10 times the maximum daily human dose.

There are no adequate or well-controlled studies in pregnant women. Withdrawal symptoms, including jitteriness, tremor, and seizures, have been reported in neonates whose mothers had taken Anafranil until delivery. Anafranil should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

#### Nursing Mothers
Anafranil has been found in human milk. Because of the potential for adverse reactions, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

#### Pediatric Use
In a controlled clinical trial in children and adolescents (10-17 years of age), 46 outpatients received Anafranil for up to 8 weeks. In addition, 150 adolescent patients have received Anafranil in open-label protocols for periods of several months to several years. Of the 196 adolescents studied, 50 were 13 years of age or less and 146 were 14-17 years of age. While the adverse reaction profile in this age group (see ADVERSE REACTIONS) is similar to that in adults, it is unknown what, if any, effects long-term treatment with Anafranil may have on the growth and development of children.

The safety and effectiveness in children below the age of 10 have not been established. Therefore, specific recommendations cannot be made for the use of Anafranil in children under the age of 10.

#### Use in Elderly
Anafranil has not been systematically studied in older patients; but 152 patients at least 60 years of age participating in U.S. clinical trials received Anafranil for periods of several months to several years. No unusual age-related adverse events have been identified in this elderly population, but these data are insufficient to rule out possible age-related differences, particularly in elderly patients who have concomitant systemic illnesses or who are receiving other drugs concomitantly.

### ADVERSE REACTIONS
#### Commonly Observed
The most commonly observed adverse events associated with the use of Anafranil and not seen at an equivalent incidence among placebo-treated patients were gastrointestinal complaints, including dry mouth, constipation, nausea, dyspepsia, and anorexia; nervous system complaints, including somnolence, tremor, dizziness, nervousness, and myoclonus; genitourinary complaints, including changed libido, ejaculatory failure, impotence, and micturition disorder; and other miscellaneous complaints, including fatigue, sweating, increased appetite, weight gain, and visual changes.

#### Leading to Discontinuation of Treatment
Approximately 20% of 3616 patients who received Anafranil in U.S. premarketing clinical trials discontinued treatment because of an adverse event. Approximately one-half of the patients who discontinued (9% of the total) had multiple complaints, none of which could be classified as primary. Where a primary reason for discontinuation could be identified, most patients discontinued because of nervous system complaints (5.4%), primarily somnolence. The second-most-frequent reason for discontinuation was digestive system complaints (1.3%), primarily vomiting and nausea.

#### Incidence in Controlled Clinical Trials
The following table enumerates adverse events that occurred at an incidence of 1% or greater among patients with OCD who received Anafranil in adult or pediatric placebo-controlled clinical trials. The frequencies were obtained from pooled data of clinical trials involving either adults receiving Anafranil (N = 322) or placebo (N = 319) or children treated with Anafranil (N = 46) or placebo (N = 44). The prescriber should be aware that these figures cannot be used to predict the incidence of side effects in the course of usual medical practice, in which patient characteristics and other factors differ from those which prevailed in the clinical trials. Similarly, the cited frequencies cannot be compared with figures obtained from other clinical investigations involving different treatments, uses, and investigators. The cited figures, however, provide the physician with a basis for estimating the relative contribution of drug and nondrug factors to the incidence of side effects in the populations studied.

### Incidence of Treatment-Emergent Adverse Experience in Placebo-Controlled Clinical Trials
(Percentage of Patients Reporting Event)

| | Adults | | Children and Adolescents | |
|---|---|---|---|---|
| **Body System/ Adverse Event*** | **Anafranil (N=322)** | **Placebo (N=319)** | **Anafranil (N=46)** | **Placebo (N=44)** |

*Events reported by at least 1% of Anafranil patients are included

**Other Events Observed During the Premarketing Evaluation of Anafranil**

During clinical testing in the U.S., multiple doses of Anafranil were administered to approximately 3600 subjects. Untoward events associated with this exposure were recorded by clinical investigators using terminology of their own choosing. Consequently, it is not possible to provide a meaningful estimate of the proportion of individuals experiencing adverse events without first grouping similar types of untoward events into a smaller number of standardized event categories.

In the tabulations that follow, a modified World Health Organization dictionary of terminology has been used to classify reported adverse events. The frequencies presented, therefore, represent the proportion of the 3525 individuals exposed to Anafranil who experienced an event of the type cited on at least one occasion while receiving Anafranil. All events are included except those already listed in the previous table, those reported in terms so general as to be uninformative, and those in which an association with the drug was remote. It is important to emphasize that although the events reported occurred during treatment with Anafranil, they were not necessarily caused by it.

Events are further categorized by body system and listed in order of decreasing frequency according to the following definitions: frequent adverse events are those occurring on one or more occasions in at least 1/100 patients; infrequent adverse events are those occurring in 1/100 to 1/1000 patients; rare events are those occurring in less than 1/1000 patients.

***Body as a Whole:*** *Infrequent* — general edema, increased susceptibility to infection, malaise. *Rare* — dependent edema, withdrawal syndrome.

***Cardiovascular System:*** *Infrequent* — abnormal ECG, arrhythmia, bradycardia, cardiac arrest, extrasystoles, pallor. *Rare* — aneurysm, atrial flutter, bundle branch block, cardiac failure, cerebral hemorrhage, heart block, myocardial infarction, myocardial ischemia, peripheral ischemia, thrombophlebitis, vasospasm, ventricular tachycardia.

***Digestive System:*** *Infrequent* — abnormal hepatic function, blood in stool, colitis, duodenitis, gastric ulcer, gastritis, gastroesophageal reflux, gingivitis, glossitis, hemorrhoids, hepatitis, increased saliva, irritable bowel syndrome, peptic ulcer, rectal hemorrhage, tongue ulceration, tooth caries. *Rare* — cheilitis, chronic enteritis, discolored feces, gastric dilatation, gingival bleeding, hiccup, intestinal obstruction, oral/pharyngeal edema, paralytic ileus, salivary gland enlargement.

***Endocrine System:*** *Infrequent* — hypothyroidism. *Rare* — goiter, gynecomastia, hyperthyroidism.

***Hemic and Lymphatic System:*** *Infrequent* — lymphadenopathy. *Rare* — leukemoid reaction, lymphoma-like disorder, marrow depression.

***Metabolic and Nutritional Disorder:*** *Infrequent* — dehydration, diabetes mellitus, gout, hypercholesterolemia, hyperglycemia, hyperuricemia, hypokalemia. *Rare* — fat intolerance, glycosuria.

***Musculoskeletal System:*** *Infrequent* — arthrosis. *Rare* — dystonia, exostosis, lupus erythematosus rash, bruising, myopathy, myositis, polyarteritis nodosa, torticollis.

***Nervous System:*** *Frequent* — abnormal thinking, vertigo. *Infrequent* — abnormal coordination, abnormal EEG, abnormal gait, apathy, ataxia, coma, convulsions, delirium, delusion, dyskinesia, dysphonia, encephalopathy, euphoria, extrapyramidal disorder, hallucinations, hostility, hyperkinesia, hypnagogic hallucinations, hypokinesia, leg cramps, manic reaction, neuralgia, paranoia, phobic disorder, psychosis, sensory disturbance, somnambulism, stimulation, suicidal ideation, suicide attempt, teeth-grinding. *Rare* — anticholinergic syndrome, aphasia, apraxia, catalepsy, cholinergic syndrome, choreoathetosis, generalized spasm, hemiparesis, hyperesthesia, hyperreflexia, hypoesthesia, illusion, impaired impulse control, indecisiveness, mutism, neuropathy, nystagmus, oculogyric crisis, oculomotor nerve paralysis, schizophrenic reaction, stupor, suicide.

***Respiratory System:*** *Infrequent* — bronchitis, hyperventilation, increased sputum, pneumonia. *Rare* — cyanosis, hemoptysis, hypoventilation, laryngismus.

***Skin and Appendages:*** *Infrequent* — alopecia, cellulitis, cyst, eczema, erythematous rash, genital pruritus, maculopapular rash, photosensitivity reaction, psoriasis, pustular rash, skin discoloration. *Rare* — chloasma, folliculitis, hypertrichosis, piloerection, seborrhea, skin hypertrophy, skin ulceration.

***Special Senses:*** *Infrequent* — abnormal accommodation, deafness, diplopia, earache, eye pain, foreign body sensation, hyperacusis, parosmia, photophobia, scleritis, taste loss. *Rare* — blepharitis, chromatopsia, conjunctival hemorrhage, exophthalmos, glaucoma, keratitis, labyrinth disorder, night blindness, retinal disorder, strabismus, visual field defect.

***Urogenital System:*** *Infrequent* — endometriosis, epididymitis, hematuria, nocturia, oliguria, ovarian cyst, perineal pain, polyuria, prostatic disorder, renal calculus, renal pain, urethral disorder, urinary incontinence, uterine hemorrhage, vaginal hemorrhage. *Rare* — albuminuria, anorgasmy, breast engorgement, breast fibroadenosis, cervical dysplasia, endometrial hyperplasia, premature ejaculation, pyelonephritis, pyuria, renal cyst, uterine inflammation, vulvar disorder.

## DRUG ABUSE AND DEPENDENCE

Anafranil has not been systematically studied in animals or humans for its potential for abuse, tolerance, or physical dependence. While a variety of withdrawal symptoms have been described in association with Anafranil discontinuation (see PRECAUTIONS, Withdrawal Symptoms), there is no evidence for drug-seeking behavior, except for a single report of potential Anafranil abuse by a patient with a history of dependence on codeine, benzodiazepines, and multiple psychoactive drugs. The patient received Anafranil for depression and panic attacks and appeared to become dependent after hospital discharge.

Despite the lack of evidence suggesting an abuse liability for Anafranil in foreign marketing, it is not possible to predict the extent to which Anafranil might be misused or abused once marketed in the U.S. Consequently, physicians should carefully evaluate patients for a history of drug abuse and follow such patients closely.

## OVERDOSAGE

### Human Experience

In U.S. clinical trials, 2 deaths occurred in 12 reported cases of acute overdosage with Anafranil either alone or in combination with other drugs. One death involved a patient suspected of ingesting a dose of 7000 mg. The second death involved a patient suspected of ingesting a dose of 5750 mg. The 10 nonfatal cases involved doses of up to 5000 mg, accompanied by plasma levels of up to 1010 ng/ml. All 10 patients completely recovered. Among reports from other countries of Anafranil overdose, the lowest dose associated with a fatality was 750 mg. Based upon post-marketing reports in the United Kingdom, CMI's lethality in overdose is considered to be similar to that reported for closely related tricyclic compounds marketed as antidepressants.

### Signs and Symptoms

Signs and symptoms vary in severity depending upon factors such as the amount of drug absorbed, the age of the patient, and the time elapsed since drug ingestion. Blood and urine levels of Anafranil may not reflect the severity of poisoning; they have chiefly a qualitative rather than quantitative value, and they are unreliable indicators in the clinical management of the patient. The first signs and symptoms of poisoning with tricyclic antidepressants are generally severe anticholinergic reactions. CNS abnormalities may include drowsiness, stupor, coma, ataxia, restlessness, agitation, delirium, severe perspiration, hyperactive reflexes, muscle rigidity, athetoid and choreiform movements, and convulsions. Cardiac abnormalities may include arrhythmia, tachycardia, ECG evidence of impaired conduction, and signs of congestive heart failure, and in very rare cases, cardiac arrest. Respiratory depression, cyanosis, hypotension, shock, vomiting, hyperpyrexia, mydriasis, oliguria or anuria, and diaphoresis may also be present.

### Treatment

The recommended treatment for tricyclic overdose may change periodically. Therefore, it is recommended that the physician contact a poison control center for current information on treatment.

Because CNS involvement, respiratory depression, and cardiac arrhythmia can occur suddenly, hospitalization and close observation may be necessary, even when the amount ingested is thought to be small or the initial degree of intoxication appears slight or moderate. All patients with ECG abnormalities should have continuous cardiac monitoring and be closely observed until well after the cardiac status has returned to normal; relapses may occur after apparent recovery.

In the alert patient, the stomach should be emptied promptly by lavage. In the obtunded patient, the airway should be secured with a cuffed endotracheal tube before beginning lavage (do not induce emesis). Instillation of activated charcoal slurry may help reduce absorption of CMI.

External stimulation should be minimized to reduce the tendency for convulsions. If anticonvulsants are necessary, diazepam and phenytoin may be useful. Adequate respiratory exchange should be maintained, including intubation and artificial respiration, if necessary. Respiratory stimulants should not be used.

In severe hypotension or shock, the patient should be placed in an appropriate position and given a plasma expander, and, if necessary, a vasopressor agent by intravenous drip. The use of corticosteroids in shock is controversial and may be contraindicated in cases of overdosage with tricyclic antidepressants. Digitalis may increase conduction abnormalities and further irritate an already sensitized myocardium. If congestive heart failure necessitates rapid digitalization, particular care must be exercised. Hyperpyrexia should be controlled by whatever external means are available, including ice packs and cooling sponge baths necessary. Hemodialysis, peritoneal dialysis, exchange transfusions, and forced diuresis have generally been reported as ineffective because of the rapid fixation of Anafranil in tissues.

The slow intravenous administration of physostigmine salicylate has been used as a last resort to reverse severe CNS anticholinergic manifestations of overdosage with tricyclic antidepressants; however, it should not be used routinely since it may induce seizures and cholinergic crises.

## DOSAGE AND ADMINISTRATION

The treatment regimens described below are based on those used in controlled clinical trials of Anafranil in 520 adults, and 91 children and adolescents with OCD. During initial titration, Anafranil should be given in divided doses with meals to reduce gastrointestinal side effects. The goal of the initial titration phase is to minimize side effects by permitting tolerance to side effects to develop or allowing the patient time to adapt if tolerance does not develop.

Because both CMI and its active metabolite, DMI, have long elimination half-lives, the prescriber should take into consideration the fact that steady-state plasma levels may not be achieved until 2-3 weeks after dosage change (see CLINICAL PHARMACOLOGY). Therefore, after initial titration, it may be appropriate to wait 2-3 weeks between further dosage adjustments.

### Initial Treatment/Dose Adjustment (Adults)

Treatment with Anafranil should be initiated at a dosage of 25 mg daily and gradually increased, as tolerated, to approximately 100 mg during the first 2 weeks. During initial titration, Anafranil should be given in divided doses with meals to reduce gastrointestinal side effects. Thereafter, the dosage may be increased gradually over the next several weeks, up to a maximum of 250 mg daily. After titration, the total daily dose may be given once daily at bedtime to minimize daytime sedation.

### Initial Treatment/Dose Adjustment (Children and Adolescents)

As with adults, the starting dose is 25 mg daily and should be gradually increased (also given in divided doses with meals to reduce gastrointestinal side effects) during the first 2 weeks, as tolerated, up to a daily maximum of 3 mg/kg or 100 mg, whichever is smaller. Thereafter, the dosage may be increased gradually over the next several weeks up to a daily maximum of 3 mg/kg or 200 mg, whichever is smaller (see PRECAUTIONS, Pediatric Use). As with adults, after titration, the total daily dose may be given once daily at bedtime to minimize daytime sedation.

### Maintenance/Continuation Treatment (Adults, Children, and Adolescents)

While there are no systematic studies that answer the question of how long to continue Anafranil, OCD is a chronic condition and it is reasonable to consider continuation for a responding patient. Although the efficacy of Anafranil after 10 weeks has not been documented in controlled trials, patients have been continued in therapy under double-blind conditions for up to 1 year without loss of benefit. However, dosage adjustments should be made to maintain the patient on the lowest effective dosage, and patients should be periodically reassessed to determine the need for treatment. During maintenance, the total daily dose may be given once daily at bedtime.

## HOW SUPPLIED

| | |
|---|---|
| *Capsules 25 mg* — ivory/melon yellow (imprinted ANAFRANIL 25 mg) | |
| Bottles of 100 | NDC 58887-115-30 |
| Unit Dose (blister pack) | |
| Box of 100 (strips of 10) | NDC 58887-115-32 |
| *Capsules 50 mg* — ivory/aqua blue (imprinted ANAFRANIL 50 mg) | |
| Bottles of 100 | NDC 58887-116-30 |
| Unit Dose (blister pack) | |
| Box of 100 (strips of 10) | NDC 58887-116-32 |
| *Capsules 75 mg* — ivory/yellow (imprinted ANAFRANIL 75 mg) | |
| Bottles of 100 | NDC 58887-117-30 |
| Unit Dose (blister pack) | |
| Box of 100 (strips of 10) | NDC 58887-117-[illegible] |

Samples, when available, are identified by the word *SAMPLE* appearing on each capsule.

Do not store above 86°F (30°C). Protect from moisture.

*Dispense in tight container (USP).*

## ANIMAL TOXICOLOGY

Testicular and lung changes commonly associated with tricyclic compounds have been observed with Anafranil. In 1- and 2-year studies in rats, changes in the testes (atrophy, aspermatogenesis, and calcification) and drug-induced phospholipidosis in the lungs were observed at doses 4 times the maximum daily human dose. Testicular atrophy was also observed in a 1-year oral toxicity study in dogs at 10 times the maximum daily human dose.

# Calendar

*For free listing of your organization's official annual or regional meeting, please send us the following information: sponsor, location, inclusive dates, type and number of continuing education credits (if available), and the name, address, and telephone number of the person or group to contact for more information. All notices and changes must be received no later than 120 days before the first day of the month of desired publication and should be addressed to Calendar, American Journal of Psychiatry, 1400 K St., N.W., Washington, DC 20005. Because of space limitations, only listings of meetings of the greatest interest to Journal readers will be included.*

## APRIL

April 2–5, 10th Annual Symposium in Forensic Psychiatry, American College of Forensic Psychiatry, San Francisco. Contact: Ed Miller, Executive Director, 26701 Quail Creek, Suite 295, Laguna Hills, CA 92656; 714-831-0236.

April 9–12, 12th National Conference on Anxiety Disorders, Anxiety Disorders Association of America, Houston. Contact: Conference Department, 6000 Executive Blvd., Rockville, MD 20852-3801; 301-231-5484.

April 12–17, conference, "Folk Medicine of Central America," Southern California Neuropsychiatric Institute, San Jose, Costa Rica. Contact: Ann McCormick, SCNPI, 6794 La Jolla Blvd., La Jolla, CA 92037; 619-454-2102 (tel), 619-454-2104 (fax).

April 24–25, conference, "Women," Cambridge Hospital and Harvard Medical School, Boston. Contact: Judy Reiner Platt, Cambridge Hospital, 1493 Cambridge St., Cambridge, MA 02139; 617-864-6165.

April 26, 4th Annual Symposium on Treatment of Headaches and Facial Pain, Downstate Headache Center, New York. Contact: Alexander Mauskop, M.D., Director, The Downstate Headache Center, 132 Atlantic Avenue, Brooklyn Heights, NY 11201; 718-935-9666.

## MAY

May 2–7, 145th Annual Meeting, American Psychiatric Association, Washington, D.C. Contact: George Campbell, Director, Meetings Management, APA, 1400 K Street, N.W., Washington, DC 20005; 202-682-6193.

May 6–10, "Spring Symposium on Back Pain" (maximum of 24 hours of CME category 1 credit), American Back Society, Columbia Regional Hospital, and Columbia Spine Center, New Orleans. Contact: Aubrey A. Swartz, M.D., Executive Director, American Back Society, 2647 E. 14th Street, Suite 401, Oakland, CA 94601; 510-536-9929 (tel), 510-536-1812 (fax).

May 8–10, international congress, International Association Autism Europe, The Hague. Contact: Mies Hoffmann, The General Secretary IAAE, Rue Emile Leger 4, B-6320 Villers-la-Ville, Belgium; 32-71-879594.

May 24–27, 27th Annual Conference of the Association for the Care of Children's Health, "Building on the Strengths of Children and Families: Child Health Policy, Programs, and Practice," Atlanta. Contact: Lee Ann Slayton, ACCH, 7910 Woodmont Ave., Suite 300, Bethesda, MD 20814-3015; 301-654-1205.

May 27–30, regional symposium, World Psychiatric Association, Palermo, Italy. Contact: WPA Secretariat, c/o Clinica Lopez-Ibor, 44 Calle Nueva Zelanda, E-28035 Madrid, Spain; 34-1-3162740.

May 28–29, conference, "Psychiatric, Psychosocial and Ethical Aspects of Organ Transplantation," University of Pittsburgh School of Medicine and the Academy of Psychosomatic Medicine, Pittsburgh. Contact: Paula T. Trzepacz, M.D., Western Psychiatric Institute and Clinic, 3811 O'Hara Street, Pittsburgh, PA 15213; 412-624-0701.

May 29–31, conference, "1992: Update in Psychiatry," Medical University of South Carolina, Institute of Psychiatry, Charleston, South Carolina. Contact: the Psychiatry Resource Development Office, 171 Ashley Avenue, Charleston, SC, 29425-0742; 803-792-4012.

## JUNE

June 3–5, symposium, "Integrated Approach to Schizophrenia," Turku. Contact: Ulla Halkola, Congress Secretariat, University of Turku, Centre for Expansion Studies, Pispalantie 7, Turku 20510, Finland; 358-21-6336217.

June 11–14, 40th Annual Convention and Workshops, "Well-Being: Theory and Practice," North American Society of Adlerian Psychology, Chicago. Contact: Linda L. Wise, Convention Coordinator, 5353 Manhattan Circle, Suite 103, Boulder, CO 80303; 303-499-2299 (tel), 303-499-2599 (fax).

June 12–13, conference, "Psychotherapy," Cambridge Hospital and Harvard Medical School, Boston. Contact: Judy Reiner Platt, Cambridge Hospital, 1493 Cambridge Street, Cambridge, MA 02139; 617-864-6165.

June 21–26, conference, "Trauma and Tragedy: The Origins, Management and Prevention in Today's World," International Society for Traumatic Stress Studies, Amsterdam. Contact: Jos M.P. Weerts, Secretary, Organizing Committee, ICODO, P.B. 13362, 3507 LJ Utrecht, The Netherlands; (+31)(0)30-369312 (tel), (+31)(0)30-369037 (fax).

June 28–July 2, 18th Collegium Internationale Neuro-Psychopharmacologicum, Nice. Contact: Organizing Secretariat, Nice Congres, 1 Esplanade Kennedy, 06300 Nice, France; 33-93-928071

# Take a New Look at PAMELOR

## Clinical improvement in depression…

| With Anxiety | With Insomnia | In the Elderly |
|---|---|---|
| 72% | 78% | 80%[1] |
| With little likelihood of agitation | With little daytime sedation | Most extensively studied and best-tolerated tricyclic antidepressant in the elderly[2] |

- Unlike serotonin reuptake inhibitors, PAMELOR does not commonly cause agitation, insomnia, or nausea[3]
- A favorable side effect profile
- Once-a-day dosing with capsules or solution

PAMELOR® (nortriptyline HCl) may impair the mental and/or physical abilities required for the performance of hazardous tasks; therefore, the patient should be warned accordingly. Because of its anticholinergic activity, PAMELOR therapy should be used with great caution in patients who have glaucoma or a history of urinary retention. As with all other antidepressants, patients with cardiovascular disease should be given PAMELOR therapy only under close supervision because of the tendency of the drug to produce sinus tachycardia and to prolong conduction time.

Please see brief summary of prescribing information on last page of this advertisement.

**PAMELOR®**
**(nortriptyline HCl)**

CAPSULES: 10 mg, 25 mg, 50 mg, and 75 mg; SOLUTION: 10 mg/5 mL with alcohol content 4%

Proven Performance in Depression

## PAMELOR® (nortriptyline HCl)

**BRIEF SUMMARY:** Please see package insert for full prescribing information.

### CONTRAINDICATIONS

1) Concurrent use with a monoamine oxidase (MAO) inhibitor, since hyperpyretic crises, severe convulsions, and fatalities have occurred when similar tricyclic antidepressants were used in such combinations; MAO inhibitors should be discontinued for at least two weeks before treatment with Pamelor® (nortriptyline HCl) is started. 2) Hypersensitivity to Pamelor® (nortriptyline HCl), cross-sensitivity with other dibenzazepines is a possibility. 3) The acute recovery period after myocardial infarction.

### WARNINGS

Give only under close supervision to patients with cardiovascular disease, because of the tendency of the drug to produce sinus tachycardia and to prolong conduction time; myocardial infarction, arrhythmia, and strokes have occurred. The antihypertensive action of guanethidine and similar agents may be blocked. Because of its anticholinergic activity, nortriptyline should be used with great caution in patients who have glaucoma or a history of urinary retention. Patients with a history of seizures should be followed closely, since nortriptyline is known to lower the convulsive threshold. Great care is required in hyperthyroid patients or those receiving thyroid medication, since cardiac arrhythmias may develop. Nortriptyline may impair the mental and/or physical abilities required for the performance of hazardous tasks, such as operating machinery or driving a car; therefore, the patient should be warned accordingly. Excessive consumption of alcohol may have a potentiating effect, which may lead to the danger of increased suicidal attempts or overdosage, especially in patients with histories of emotional disturbances or suicidal ideation.

The concomitant administration of quinidine and nortriptyline may result in a significantly longer plasma half-life, higher A.U.C. and lower clearance of nortriptyline.

*Use in Pregnancy* — Safe use during pregnancy and lactation has not been established; therefore, in pregnant patients, nursing mothers, or women of child-bearing potential, the potential benefits must be weighed against the possible hazards.

*Use in Children* — Not recommended for use in children, since safety and effectiveness in the pediatric age group have not been established.

### PRECAUTIONS

Use in schizophrenic patients may result in an exacerbation of the psychosis or may activate latent schizophrenic symptoms; in overactive or agitated patients, increased anxiety and agitation may occur; in manic-depressive patients, symptoms of the manic phase may emerge. Administration of reserpine during therapy with a tricyclic antidepressant has been shown to produce a "stimulating" effect in some depressed patients. Troublesome patient hostility may be aroused. Epileptiform seizures may accompany administration. Close supervision and careful adjustment of dosage are required when used with other anticholinergic drugs and sympathomimetic drugs. Concurrent administration of cimetidine can produce clinically significant increases in the plasma concentrations of the tricyclic antidepressant. Patients should be informed that the response to alcohol may be exaggerated. When essential, may be administered with electroconvulsive therapy, although the hazards may be increased. Discontinue the drug for several days, if possible, prior to elective surgery. The possibility of a suicidal attempt by a depressed patient remains after the initiation of treatment; in this regard, it is important that the least possible quantity of drug be dispensed at any given time. Both elevation and lowering of blood sugar levels have been reported. A case of significant hypoglycemia has been reported in a type II diabetic patient maintained on chlorpropamide (250 mg/day), after the addition of nortriptyline (125 mg/day).

### ADVERSE REACTIONS

*Cardiovascular* — Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. ***Psychiatric*** — Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia, panic, nightmares; hypomania; exacerbation of psychosis. ***Neurologic*** — Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alteration in EEG patterns; tinnitus. ***Anticholinergic*** — Dry mouth and, rarely, associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract. ***Allergic*** — Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue), drug fever, cross-sensitivity with other tricyclic drugs. ***Hematologic*** — Bone marrow depression, including agranulocytosis; eosinophilia; purpura; thrombocytopenia. ***Gastrointestinal*** — Nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black-tongue. ***Endocrine*** — Gynecomastia in the male, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels; syndrome of inappropriate ADH (antidiuretic hormone) secretion. ***Other*** — Jaundice (simulating obstructive), altered liver function; weight gain or loss; perspiration; flushing; urinary frequency, nocturia; drowsiness, dizziness, weakness, fatigue; headache; parotid swelling; alopecia. ***Withdrawal Symptoms*** — Though these are not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

### OVERDOSAGE

Toxic overdosage may result in confusion, restlessness, agitation, vomiting, hyperpyrexia, muscle rigidity, hyperactive reflexes, tachycardia, ECG evidence of impaired conduction, shock, congestive heart failure, stupor, coma, and CNS stimulation with convulsions followed by respiratory depression. Deaths have occurred with drugs of this class. No specific antidote is known; general supportive measures are indicated, with gastric lavage

# THE MANFRED S. GUTTMACHER AWARD

The American Psychiatric Association and the American Academy of Psychiatry and the Law invite submissions for the 1993 Manfred S. Guttmacher Award. This award is given for an outstanding contribution to the literature of forensic psychiatry in the form of a book, monograph, paper, or any other work presented at a professional meeting or published between May 1, 1991 and April 30, 1992. The award will be formally presented in May 1993 at the American Academy of Psychiatry and the Law meeting held in conjunction with the American Psychiatric Association Annual Meeting in San Francisco, CA. The award includes an honorarium of $500 and a plaque. The travel expenses of non-member winners will be reimbursed up to $500. The recipient is expected to present an award lecture. The award will be cited in the Convocation of Fellows program of the 1993 APA Annual Meeting and the lecture will be listed in the APA Convocation Program.

Anyone wishing to apply should submit 6 copies of the work, along with 6 copies of an abstract, to:

*W. Walter Menninger, M.D.*
*Chairman*
*Guttmacher Award Board*
*American Psychiatric Association*
*1400 K Street, N.W., Suite 327*
*Washington, DC 20005*

Entries must be recieved by May 15, 1992. Entries will be acknowledged but not returned.

THE SUDDEN TORMENT OF

Panic

HOPE FROM A FAMILIAR SOURCE

XANAX IS THE FIRST AND ONLY MEDICATION INDICATED FOR PANIC DISORDER

- Usually blocks panic attacks, often within the first week of therapy[1]
- No cardiovascular toxicity

| | |
|---|---|
| Usual starting dosage for panic disorder | 0.5 mg tid |
| Average dosage in clinical studies at week 8 | 5.7 mg/day |

Side effects reported with XANAX are those generally associated with benzodiazepine therapy, such as drowsiness and impaired coordination.

XANAX 2-mg MULTISCORED TABLETS FOR COST-EFFECTIVE THERAPY

# First for Panic

**XANAX® Tablets**
**(alprazolam, ⒸIV Upjohn)**

### INDICATIONS AND USAGE

Generalized anxiety disorder, short-term relief of the symptoms of anxiety, and anxiety associated with depression. Anxiety or tension associated with the stress of everyday life does not usually require an anxiolytic.

Panic disorder, with or without agoraphobia.

Effectiveness has been established for up to 4 months for anxiety disorder and 4 to 10 weeks for panic disorder; but panic disorder has been treated open label for up to 8 months with no apparent loss of benefit. The usefulness should be reassessed periodically.

### CONTRAINDICATIONS

Sensitivity to XANAX or other benzodiazepines and in acute narrow-angle glaucoma.

### WARNINGS

***Dependence and withdrawal reactions, including seizures***

Physical dependence on XANAX can produce certain adverse clinical events, some life-threatening. These include a spectrum of withdrawal symptoms—the most important is seizure. Even after relatively short-term use at 0.75 to 4 mg per day, there is some risk of dependence; but the risk and severity seem to be greater in patients treated with doses above 4 mg/day for more than 8 to 12 weeks.

***Treatment of panic disorder: Dose and risks of XANAX***

Panic-disorder patients often need doses greater than 4 mg/day, hence the risk of dependence may be greater than in patients treated for less severe anxiety. Based on studies involving 641 patients, the most frequent symptoms seen during discontinuation were:

***Neurologic:*** Insomnia, light-headedness, abnormal involuntary movement, headache, muscular twitching, impaired coordination, muscle-tone disorders, weakness.

***Psychiatric:*** Anxiety, fatigue and tiredness, irritability, cognitive disorder, memory impairment, depression, confusional state.

***Gastrointestinal:*** Nausea/vomiting, diarrhea, decreased salivation.

***Other systems:*** Weight loss, decreased appetite, sweating, tachycardia, blurred vision. It has not been determined if these symptoms are clearly related to dose and duration of therapy. In two controlled trials of the discontinuation of XANAX lasting 6 to 8 weeks, 71% to 93% of patients treated with XANAX compared with 89% to 96% of placebo patients tapered completely off medication. The ability of patients to completely discontinue after long-term therapy has not been reliably determined.

Seizures were reported in 8 of 1,980 patients who took more than 4 mg XANAX daily for over 3 months, generally during abrupt dose reduction. There have been occasional reports of seizures during gradual taper; the risk seems to be greatest 24 to 72 hours after discontinuation.

***Status epilepticus and its treatment:*** Discontinuation of XANAX has been associated with seizures. In most cases a single seizure was reported; however, multiple seizures and status epilepticus have been reported. Treatment is the same as that for status of any cause.

***Interdose symptoms:*** Early morning anxiety and emergence of anxiety symptoms between doses have been reported in panic patients taking XANAX. It can usually be managed with more frequent administration of the same total daily dose or by increasing total dosage.

***Risks of dose reduction:*** Withdrawal reactions may occur with dosage reduction for any reason; dosage should be reduced gradually. (See DOSAGE AND ADMINISTRATION.)

XANAX is not of value in treating psychosis and should not be used in lieu of appropriate treatment. Patients receiving XANAX should be cautioned about hazardous occupations or activities requiring full alertness and also about simultaneous ingestion of alcohol or other CNS depressants.

Benzodiazepines can cause fetal harm in pregnant women, hence women who may become pregnant should be warned. Avoid during the first trimester. (See DRUG ABUSE AND DEPENDENCE and DOSAGE AND ADMINISTRATION.)

### PRECAUTIONS

***General:*** If XANAX is combined with other psychotropics or anticonvulsants, consider drug potentiation. (See DRUG INTERACTIONS.) Use the usual precautions in patients with impaired renal, hepatic, or pulmonary function and regarding prescription size in depressed and suicidal patients. Use the smallest effective dose to avoid ataxia or oversedation, which may be a particular problem in elderly or debilitated patients. Alprazolam plasma half-life may be prolonged in obese patients or those with alcoholic liver disease. There have been rare reports of death in patients with severe pulmonary disease shortly after the start of therapy with XANAX. Episodes of mania and hypomania have been reported in depressed patients. Alprazolam is weakly uricosuric.

***Information for patients:*** For all users of XANAX. Alert patients about: (1) consumption of alcohol and drugs, (2) not taking any benzodiazepine during pregnancy or while nursing, (3) operating machinery or driving, (4) not increasing the dose due to risk of dependence, (5) not stopping the drug abruptly.

Additional advice for panic patients:

Use of more than 4 mg per day of XANAX for long periods of time may cause severe emotional and physical dependence in some patients, and these patients may find it difficult to stop treatment. In two studies lasting 6 to 8 weeks, 7% to 29% of patients treated with XANAX did not completely taper off therapy. The ability of patients to completely discontinue therapy has not been determined. Also, extended use of high doses appears to increase the incidence and severity of withdrawal reactions when XANAX is discontinued. These are generally minor, but seizure, which can be life-threatening, can occur, especially if dose is reduced too rapidly or stopped abruptly.

***Laboratory tests:*** Not ordinarily required in otherwise healthy patients.

***Drug interactions:*** Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol, and other CNS depressants. Plasma levels of imipramine and desipramine are increased. Pharmacokinetic interactions with other drugs have been reported. Cimetidine and oral contraceptives can delay clearance of benzodiazepines. ***Drug/laboratory test interactions:*** No consistent pattern. ***Carcinogenesis, mutagenesis, impairment of fertility:*** No carcinogenic potential or impairment of fertility in rats. ***Pregnancy:*** See WARNINGS. ***Nonteratogenic effects:*** The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms, neonatal flaccidity, and respiratory problems. ***Labor and delivery:*** No established use. ***Nursing mothers:*** Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. ***Pediatric use:*** Safety and effectiveness in children below the age of 18 have not been established.

### ADVERSE REACTIONS

Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacologic activity of XANAX, eg, drowsiness or light-headedness.

***Central nervous system:*** Drowsiness, light-headedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness. Impaired coordination, irritability, memory impairment, cognitive disorder, dysarthria, anxiety, abnormal involuntary movement, changed libido, muscular twitching, weakness, muscle-tone disorders, agitation, disinhibition, paresthesia, talkativeness, vasomotor disturbances, derealization, dream abnormalities, fear, feeling warm.

***Gastrointestinal:*** Dry mouth, constipation, diarrhea, nausea/vomiting, increased salivation, decreased salivation, and abdominal distress.

***Cardiorespiratory:*** Tachycardia/palpitations, hypotension, nasal congestion, chest pain, hyperventilation, upper respiratory infection.

***Other:*** Blurred vision, rigidity and tremor, tinnitus, muscular stiffness and cramps, sweating, skin disorders, rash, change in appetite, micturition difficulties, menstrual disorders, sexual dysfunction, edema, incontinence, infection, dermatitis/allergy, weight gain, and weight loss.

Withdrawal seizures with rapid decrease or abrupt discontinuation. (See WARNINGS.)

To discontinue treatment, dosage must be reduced slowly by no more than 0.5 mg every 3 days.

The following adverse events have been reported with benzodiazepines: dystonia, concentration difficulties, anorexia, slurred speech, jaundice, pruritus, diplopia.

Untreated panic disorder has been associated with depressive disorders and suicide. When treating panic patients, the same caution must be used as in treating patients with depression or suicidal ideation.

Paradoxical reactions such as stimulation, agitation, rage, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analysis are advisable. Minor EEG changes, of unknown significance, have been observed.

Liver enzyme elevations, gynecomastia, and galactorrhea have been reported; but no causal relationship was established.

### DRUG ABUSE AND DEPENDENCE

***Physical and psychologic dependence:*** Withdrawal symptoms like those noted with sedative/hypnotics and alcohol have been seen after discontinuance of benzodiazepines. Symptoms can range from mild dysphoria and insomnia to a major syndrome including abdominal and muscle cramps, vomiting, sweating, tremors, and convulsions. The distinction between withdrawal symptoms and recurrence of illness is difficult. Withdrawal typically includes new symptoms, occurs toward the end of taper or shortly after discontinuation, and decreases with time. Recurrent panic disorder recurs early or late, with persistent symptoms similar to the initial presentation. When necessary XANAX should be restarted in adequate dosage.

Withdrawal symptoms, including seizures, may occur after brief therapy with dosages of 0.75 to 4 mg/day, but severity and incidence are apparently increased after dosages above 4 mg/day, after rapid decrease of dosage or abrupt discontinuation. Dosage should be gradually tapered under close supervision, especially in patients with a history of seizures or epilepsy.

Psychologic dependence is a risk with all benzodiazepines, increasing at higher doses, with long-term use, and in patients with a history of alcohol or drug abuse. Addiction-prone patients should be closely supervised when receiving XANAX and repeat prescriptions limited.

***Controlled Substance Class:*** XANAX is a controlled substance and has been assigned to schedule IV.

### OVERDOSAGE

Manifestations include somnolence, confusion, impaired coordination, diminished reflexes, and coma. Death has been reported with overdosage of benzodiazepines by themselves or in combination with overdosage of alcohol.

### DOSAGE AND ADMINISTRATION

Dosage should be individualized, using the lowest effective dose. The need for treatment should be reassessed frequently.

Anxiety: The usual starting dosage is 0.25 to 0.5 mg t.i.d. Maximum daily dose is 4 mg. Patients who are elderly or debilitated, or have advanced liver disease, may be especially sensitive to benzodiazepines, and the starting dosage is 0.25 mg b.i.d. or t.i.d. Reduce dosage gradually, by no more than 0.5 mg every 3 days, or more slowly.

Panic disorder: Many patients required more than 4 mg daily. Mean dosage in studies was 5 to 6 mg/day, with a maximum of 10 mg/day. Treatment may be initiated with 0.5 mg t.i.d. Depending on the response, dosage may be increased every 3 or 4 days by up to 1 mg daily. After extended freedom from attacks, dosage should be carefully tapered by, at most, 0.5 mg every 3 days. Some patients may be resistant to all discontinuation regimens.

### HOW SUPPLIED

XANAX Tablets are available as 0.25-mg, 0.5-mg, 1-mg, and 2-mg tablets.

## coding for your specialty

### *CPT Assistant* takes a special interest in psychiatry

*CPT Assistant*—the only physician coding newsletter written and produced by the American Medical Association—will take an in-depth look at the unique codes used to report psychiatric services in its Summer 1992 issue.

Subscribe now and you will be sure to receive this important issue developed especially for psychiatric practitioners and the staff who report their services. Important features include:

- how to use the psychiatric codes found in *CPT 1992*
- the rationale behind CPT's new psychiatric codes
- how to use the new evaluation and management codes with the psychiatric codes

### Specialty coding and a whole lot more!

This special focus on psychiatric practice is only the beginning of *CPT Assistant*'s on-going value. Each quarterly issue—filled with how-to feature articles, regular columns, and informative charts and tables—offers a thorough systematic approach to procedure coding.

Stay up-to-date with coding. Order *CPT Assistant* and see the difference it can make in accurately reporting your services.

Priority Code JC117

## ESKALITH CR®

brand of LITHIUM CARBONATE 450 mg.
Controlled Release Tablets

Before prescribing, see complete prescribing information in SK&F literature or PDR. The following is a brief summary.

**WARNING**

Lithium toxicity is closely related to serum lithium levels, and can occur at doses close to therapeutic levels. Facilities for prompt and accurate serum lithium determinations should be available before initiating therapy (see DOSAGE AND ADMINISTRATION in the complete prescribing information).

**Indications**
Treatment of manic episodes of manic-depressive illness. Maintenance therapy prevents or diminishes the intensity of subsequent episodes in those manic-depressive patients with a history of mania.

**Warnings**
Lithium should generally not be given to patients with significant renal or cardiovascular disease, severe debilitation or dehydration, or sodium depletion.

Chronic lithium therapy may be associated with diminution of renal concentrating ability. Such patients should be carefully managed to avoid dehydration with resulting lithium retention and toxicity. Morphologic changes with glomerular and interstitial fibrosis and nephron atrophy have been reported. Morphologic changes have also been seen in manic-depressive patients never exposed to lithium. During lithium therapy, progressive or sudden changes in renal function, even within the normal range, indicate the need for reevaluation of treatment.

An encephalopathic syndrome (characterized by weakness, lethargy, fever, tremulousness and confusion, extrapyramidal symptoms, leukocytosis, elevated serum enzymes, BUN and FBS) has occurred in a few patients treated with lithium plus a neuroleptic. In some instances, the syndrome was followed by irreversible brain damage. Patients receiving such combined therapy should be monitored closely for early evidence of neurologic toxicity and treatment discontinued promptly if such signs appear. Caution patients about activities requiring alertness.

Lithium may prolong the effects of neuromuscular blocking agents. Such agents should be given with caution to patients receiving lithium.

Lithium carbonate may cause fetal harm when administered to a pregnant woman. If a patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus.

Nursing should not be undertaken during lithium therapy except in rare and unusual circumstances.

Not recommended in children under 12.

Elderly patients often require lower lithium dosages to achieve therapeutic serum levels. They may also exhibit adverse reactions at serum levels ordinarily tolerated by younger patients

**Precautions**
Caution should be used when lithium and diuretics are used concomitantly. Patients receiving such combined therapy should have serum lithium levels monitored closely and the lithium dosage adjusted if necessary.

Sweating, diarrhea and concomitant infection with elevated temperatures may also necessitate a temporary reduction or cessation of medication.

Indomethacin and piroxicam have been reported to increase significantly, steady state plasma lithium levels. There is also some evidence that other nonsteroidal anti-inflammatory agents may have a similar effect. When such combinations are used, increased plasma lithium level monitoring is recommended. Concurrent use of metronidazole with lithium may provoke lithium toxicity due to reduced renal clearance. Monitor patients receiving such combined therapy closely.

**Adverse Reactions**
Adverse reactions may be encountered at serum lithium levels below 1.5 mEq./l. Mild to moderate adverse reactions may occur at levels from 1.5 to 2.5 mEq./l., and moderate to severe reactions may be seen at levels of 2.0 mEq./l. and above. Fine hand tremor, polyuria, and mild thirst may occur during initial therapy and may persist throughout treatment. Transient and mild nausea and general discomfort may also appear during initial therapy. These side effects usually subside with continued treatment or a temporary reduction or cessation of dosage. Diarrhea, vomiting, drowsiness, muscular weakness, and lack of coordination may be early signs of lithium intoxication, and can occur at lithium levels below 2.0 mEq./l. At higher levels, ataxia, giddiness, tinnitus, blurred vision, and a large output of dilute urine may be seen. Serum lithium levels above 3.0 mEq./l. may produce a complex clinical picture, involving multiple organs and organ systems. Serum lithium levels should not be permitted to exceed 2.0 mEq./l. during the acute treatment phase.

The following reactions appear to be related to serum lithium levels, including levels within the therapeutic range. *Neuromuscular/Central Nervous System*—tremor, muscle hyperirritability (fasciculations, twitching, clonic movements of whole limbs), hypertonicity, ataxia, choreo-athetotic movements, hyperactive deep tendon reflex, extrapyramidal symptoms including acute dystonia, cogwheel rigidity, blackout spells, epileptiform seizures, slurred speech, dizziness, vertigo, downbeat nystagmus, incontinence of urine or feces, somnolence, psychomotor retardation, restlessness, confusion, stupor, coma, tongue movements, tics, tinnitus, hallucinations, poor memory, slowed intellectual functioning, startled response, worsening of organic brain syndromes; *Cardiovascular*—cardiac arrhythmia, hypotension, peripheral circulatory collapse, bradycardia, sinus node dysfunction with severe bradycardia (which may result in syncope); *Gastrointestinal*—anorexia, nausea, vomiting, diarrhea, gastritis, salivary gland swelling, abdominal pain, excessive salivation, flatulence, indigestion; *Genitourinary*—glycosuria, decreased creatinine clearance, albuminuria, oliguria, and symptoms of nephrogenic diabetes insipidus including polyuria, thirst, and polydipsia; *Dermatologic*—drying and thinning of hair, alopecia, anesthesia of skin, acne, chronic folliculitis, xerosis cutis, psoriasis or its exacerbation, generalized pruritus with or without rash, cutaneous ulcers, angioedema; *Autonomic*—blurred vision, dry mouth, impotence/sexual dysfunction; *Thyroid Abnormalities*—euthyroid goiter and/or hypothyroidism (including myxedema) accompanied by lower $T_3$ and $T_4$. $I^{131}$uptake may be elevated. (See Precautions.) Paradoxically, rare cases of hyperthyroidism have been reported; *EEG Changes*—diffuse slowing, widening of the frequency spectrum, potentiation and disorganization of background rhythm; *EKG Changes*—reversible flattening, isoelectricity or inversion of T-waves; *Miscellaneous*—fatigue, lethargy, transient scotomata, dehydration, weight loss, leukocytosis, headache, transient hyperglycemia, hypercalcemia, hyperparathyroidism, excessive weight gain, edematous swelling of ankles or wrists, metallic taste, dysgeusia/taste distortion, salty taste, thirst, swollen lips, tightness in chest, swollen and/or painful joints, fever, polyarthralgia, dental caries.

Some reports of nephrogenic diabetes insipidus, hyperparathyroidism and hypothyroidism which persist after lithium discontinuation have been received.

A few reports have been received of the development of painful discoloration of fingers and toes and coldness of the extremities within one day of the starting of treatment with lithium. The mechanism through which these symptoms (resembling Raynaud's syndrome) developed is not known. Recovery followed discontinuance.

Cases of pseudotumor cerebri (increased intracranial pressure and papilledema) have been reported with lithium use. Lithium should be discontinued, if clinically possible, if this syndrome occurs.

**How Supplied**
Capsules contained 300 mg. lithium carbonate per capsule, in bottles of 100 and 500.

Tablets containing 300 mg. lithium carbonate per tablet, in bottles of 100.

Controlled Release Tablets containing 450 mg. lithium carbonate per tablet, in bottles of 100.

# The Efficacy of Brief Dynamic Psychotherapy: A Meta-Analysis

**Paul Crits-Christoph, Ph.D.**

*Objective: Insurance companies, legislators, and funding agencies have become increasingly concerned with efficacy and accountability in regard to psychotherapy, and psychodynamic therapy is a primary target of concern because it is widely practiced in outpatient settings. This paper is a meta-analytic review of recent well-controlled studies of the efficacy of brief dynamic therapy. Method: The meta-analysis included both published studies, located through an extensive computerized search of psychiatry and psychology journals, and studies reported at conferences. Eleven studies met the inclusion criteria: use of a specific form of short-term dynamic psychotherapy as represented in a treatment manual or manual-like guide; comparison of brief dynamic therapy and a waiting list control condition, nonpsychiatric treatment, alternative psychotherapy, pharmacotherapy, or other form of dynamic therapy; provision of the information necessary for calculation of effect sizes; at least 12 therapy sessions; and therapists who were trained and experienced in brief dynamic therapy. The outcome measures compared were target symptoms, psychiatric symptoms generally, and social functioning. Results: Brief dynamic therapy demonstrated large effects relative to waiting list conditions but only slight superiority to nonpsychiatric treatments. Its effects were about equal to those of other psychotherapies and medication. Conclusions: These data confirm previous indications that various psychotherapies do not differ in effectiveness, although this finding should not be generalized to all patient populations, outcome measures, and treatment types. Also, the highly controlled conditions of these studies limit conclusions about actual practice. Future studies should address various treatment lengths, follow-up assessments, and specific treatments, patient groups, and outcome measures.*
(Am J Psychiatry 1992; 149:151–158)

Over the past decade, insurance companies, legislators, and funding agencies have become increasingly concerned with efficacy and accountability in regard to psychotherapy (1). Psychodynamic therapy, because it is widely practiced in outpatient settings, is a natural target for such concerns about efficacy. Although there have been a number of reviews of the literature on the efficacy of psychotherapy in general (2, 3) and the efficacy of specific treatments (4, 5), few reviews have been devoted to the efficacy of psychodynamic therapy in particular. An obvious reason for this is the relative dearth until recent years of well-controlled studies of the outcome of dynamic psychotherapy. In addition, a variety of methodological problems hindered the interpretation of results from earlier studies.

---

Received Feb. 8, 1991; revision received June 17, 1991; accepted July 16, 1991. From the Department of Psychiatry, School of Medicine, University of Pennsylvania. Perhaps the greatest problem with many efficacy studies of dynamic therapy has been the lack of control and specification of the treatment variable. The improvements in outcome research due to the use of treatment manuals and careful selection, supervision, and monitoring of therapists are relatively recent (6). Many otherwise well-controlled studies of the efficacy of dynamic therapy (e.g., 7–10) left unanswered questions about the meaning of the findings because the nature of the treatment provided by dynamic therapists was not clearly specified and controlled. These studies in general allowed dynamic therapists to conduct treatment as they usually practiced, on the assumption that differing orientations and styles among dynamic therapists are of little concern. Although such naturalistic treatment studies perhaps generalize better to the eclectic practice of dynamic therapy as it actually occurs, recommendations about specific treatment approaches cannot be based on such studies. In addition, recent evidence (11) indicates that studies which do not use treatment manuals are much more prone to therapist effects (i.e., significant differences between therapists in outcomes) than are studies which do use treatment manuals. Such therapist effects create a statistical problem of nonindependence, which can lead to highly distorted conclusions about the efficacy of treatments when ignored in the analysis of comparative outcome data (as is typically the case) (12). Thus, many of the findings from studies of dynamic therapy that did not use manuals are questionable on statistical grounds and do not provide clear clinical recommendations because of the eclectic treatment. Moreover, although the use of a dynamic therapy treatment manual does not necessarily lead to greater treatment benefits, the more careful selection, training, and monitoring of therapists in the recent comparative studies using manuals are likely to provide the highest quality of treatment possible.

In the area of brief dynamic therapy, a number of specific dynamic approaches have now been articulated in the form of guides or manuals to be used in the training of therapists: Luborsky (13), Strupp and Binder (14), Sifneos (15), Davanloo (16), Mann (17), Horowitz (18), and others. Although not all of these books have been labeled "manuals," what they have in common are a clearly laid out theory, detailed case examples, and a set of technical recommendations for the practice of a *particular* dynamic therapy (19). In addition, these guides lend themselves well to use in a research context, and studies implementing these approaches are beginning to accumulate.

Because of these improvements in outcome research, I was able to conduct a meta-analytic review (20) of the evidence for the efficacy of short-term dynamic therapy, attending only to studies that controlled the treatment variable through the use of a manual or manual-like guide for therapists. Three main questions were addressed: 1) To what extent is there evidence that brief dynamic therapy is more effective than no treatment? 2) How does brief dynamic therapy compare to regular contact with patients that is not standard psychiatric treatment? and 3) How does brief dynamic therapy compare to other forms of psychiatric treatment, including medication and nondynamic psychotherapies? In addition to summarizing the literature on these questions, I will make recommendations about future research that would advance this area of study.

## METHOD

### *Selection of Studies*

To qualify for this review, a study had to test the efficacy of a specific form of short-term dynamic therapy as represented in a treatment manual or manual-like guide. Studies comparing brief dynamic therapy to a waiting list control condition, a nonpsychiatric treatment, an alternative psychotherapy, pharmacotherapy, or another form of dynamic therapy (or some combination of these comparison conditions) were included. In addition, only reports that included the information necessary for the calculation of effect sizes (discussed later) were included. The review was not restricted to published studies but included studies that had been presented at conferences. The published studies were found through an extensive computerized search of psychiatry and psychology journals.

Any study that did not involve a patient group (e.g., analogue study) was excluded from the review. The shortest study accepted for the review was the 12-session treatment described by Mann (17). Also excluded from the review were studies that used therapists who were not specifically trained and experienced in brief dynamic therapy techniques. This excluded studies which either used trainees or used experienced therapists who had not received training in short-term dynamic therapy. This criterion was chosen because most therapists with a psychodynamic orientation tend to adhere to long-term treatment and are slow to adapt to the philosophy of short-term therapies (21).

The 11 studies that met the inclusion criteria are listed in table 1 with the type of patients, treatment conditions, number of patients in each condition, and length of therapy for each study. These studies included tests of the efficacy of the brief dynamic treatments described by Mann (17), Davanloo (16), Luborsky (13), Horowitz (18), Pollack and Horner (32), Strupp and Binder (14), Malan (33), and Klerman, Weissman, Rounsaville, and Chevron (34). The interpersonal approach of Klerman et al., although less like other dynamic therapies in that the relationship with the therapist is not generally a focus of intervention, was included because of its historical roots in the work of Sullivan. In addition, the NIMH Treatment of Depression Collaborative Research Program (35) identified the interpersonal approach as generally within the psychodynamic domain, and psychodynamically oriented therapists were selected to perform the treatment in that study.

The 11 studies typically had a training period for

[b] Mean number of sessions not reported, but data on dropouts suggest low-contact patients attended a mean of approximately four sessions.

therapists before the actual outcome study, but, as indicated in the selection criteria, they did not use inexperienced therapists. On the contrary, most studies used highly experienced therapists. In four studies the average length of postgraduate clinical experience was more than 9 years. Four other studies listed only the minimum number of postgraduate years required for therapists who participated in the study (typically 2 years). One study used therapists who were not only experienced clinicians but also had supervised training in the particular form of brief dynamic therapy for 2 years before the start of the study. Another study employed therapists who had on the average 5.5 years of experience in working with the types of patients studied. One study did not specify the therapist experience level other than to say "an experienced psychiatrist."

### *Outcome Measures*

Rather than asking the broad question, Does brief dynamic therapy work? I asked three more specific questions: 1) Does short-term dynamic therapy affect the specific target symptoms or problem areas for which patients are seeking treatment? 2) Does short-term dynamic therapy change the general level of psychiatric symptoms, and 3) Does short-term dynamic therapy improve social functioning?

The goal of this meta-analytic review was, as much as possible, to assess the effects of brief dynamic therapy on specific outcome measures. Since different outcome measures may vary in their reliability and sensitivity to change (36), it has been recommended (37) that meta-analyses not combine information on different outcome measures. Although the practice of combining information on heterogeneous outcome measures was common in early meta-analyses (e.g., 2), more recent meta-analytic reviews (e.g., 5) have begun to focus on specific measures.

In selecting measures that could provide answers to my three questions, I had to chose measures that were available in most studies. To assess specific target symptoms or problem areas for which patients seek treatment, I examined two forms of outcome measures. For studies of heterogeneous patient groups, the target complaints method (38) was selected. This measure requires the patient to rate the severity of the three main problems for which he or she is seeking treatment. For studies that investigated dynamic therapy for a specific patient group (e.g., cocaine abusers), the main problem area was already defined by the nature of patient selection. In these studies, a measure of the severity of this particular problem area or disorder (e.g., the Beck Depression Inventory for depressed patients) was selected to represent change in target symptoms.

To answer the question about the effect of brief dynamic therapy on general levels of psychiatric symptoms, the SCL-90 (39) was chosen. The Social Adjustment Scale (40) was selected to assess social functioning. In each of

**TABLE 2. Effect Sizes for Comparisons of Brief Dynamic Psychotherapy and Other Treatment Conditions**

| Condition Compared With Brief Dynamic Psychotherapy | Number of Comparisons | Average Effect Size (d)[a] | | |
|---|---|---|---|---|
| | | Target Symptoms | General Psychiatric Symptoms | Social Adjustment |
| Waiting list control | 5 | 1.10 | 0.82 | 0.81 |
| Alternative nonpsychiatric treatments | 5 | 0.32 | 0.20 | 0.09 |
| Alternative psychiatric treatments | 9 | –0.05 | –0.01 | –0.05 |
| Other dynamic therapy | 1 | –0.25 | 0.05 | 0.04 |

[a] Calculated according to the method of Cohen (41).

the few cases where these measures were not discussed in the published version of the study, the original investigators were contacted and asked to provide data on the measure if it was used in the study. In two studies the Social Adjustment Scale was not used, but ratings on alternative measures of social functioning were available, and change on these other instruments was evaluated for this review. If no measure of the construct was available, no effect size was calculated.

In general, only assessments of outcome done at or near the termination of treatment were used for this review. Although it might be of interest to examine the effects of dynamic therapy some time after termination, since delayed effects might be expected, not enough reports of follow-up data are available yet.

### *Effect Size Calculations*

The primary defining characteristics of a meta-analysis are the calculation of effect sizes and the integration of these effect sizes across studies. For this study the calculation of effect sizes was guided by Cohen (41) and used his d statistic. Effect size was calculated as the posttreatment mean of the dynamic treatment group minus the posttreatment mean of the comparison group, divided by the standard deviation of the comparison group. In some cases, only the adjusted posttreatment means and standard deviations (adjusted for initial levels) were available, and these were used instead of the raw means. A pooled standard deviation (across treatment groups) was used when the standard deviation for the comparison group was not available.

Effect size calculated this way can be readily interpreted as the distance, in standard deviation units, that the average brief dynamic therapy patient was from the average comparison group patient. An effect size of zero indicates that the dynamic therapy and comparison groups were equal in outcome. All calculations were made so that a positive effect size indicates superiority of brief dynamic therapy and a negative effect size indicates superiority of the comparison condition. Thus, an effect size of 0.50 would indicate that the improvement of the average dynamic therapy patient was one-half of the standard deviation more than that of the average comparison group patient. Because the effect size is in units of standard deviations, it can be converted directly into a percentage representing nonoverlap of the distributions (41). For example, an effect size of 1.00 would indicate that the average dynamic therapy patient was better off than 84% of the comparison group patients.

As an aid in interpreting effect sizes, Cohen (41) provided benchmarks for his d statistic. A value of 0.2 represents a small effect for the behavioral sciences, 0.5 a medium effect, and 0.8 a large effect. I will present alternative views of the meaning of different effect sizes in the Conclusions section.

## RESULTS

Table 2 presents the effect sizes from the comparisons of brief dynamic therapy and the other conditions tested.

### *Waiting List*

Five comparisons, from four studies (22, 25, 27, Shefler and Dasberg), are included in the results shown in table 2. The effect size for target symptoms is especially large, has been reported in previous studies (e.g., 42), indicating that these measures are particularly sensitive to change.

When the effect sizes are translated into percentages, the data indicate that in terms of target symptoms the average brief dynamic therapy patient was better off than 86% of the waiting list patients. In terms of general symptoms (SCL-90), the average brief dynamic therapy patient was better off than 79% of the waiting list patients. For social adjustment, the average brief dynamic therapy patient was also better off than 79% of the waiting list patients.

### *Nonpsychiatric Treatments*

Five studies compared brief dynamic therapy to some form of comparison condition that was not a standard psychiatric treatment modality (i.e., not medication or an alternative psychotherapy). The expectation in all of these studies was that dynamic therapy would produce greater effects than the comparison conditions. These comparison conditions ranged from the placebo and clinical management condition of the NIMH Treatment of Depression Collaborative Research Program study (23) to standard drug counseling (30), mutual self-help groups (31), and two studies employing a low-contact treatment (24, 28).

Overall, the average effect sizes indicate little difference between the outcomes of brief dynamic therapy and these comparison conditions. The largest average effect was for target symptoms, indicating that the average dynamic therapy patient was better off than 62% of the comparison group patients. The average effects, however, may be misleading, as there is considerable variation among these studies, perhaps as a result of the various types of comparison conditions, patient groups, etc. The effect sizes were fairly large in two studies, i.e., a comparison of the effects of dynamic therapy and drug counseling (30) on general psychiatric symptoms (effect size=0.74) and a comparison of the effects of interpersonal therapy and low-contact therapy (28) on target symptoms (effect size=0.67). In addition, in three of the five studies there was a much higher dropout rate from the alternative treatment than from dynamic therapy.

### *Other Psychiatric Treatments*

Six studies (23, 26–30) yielded nine comparisons of brief dynamic therapy and other standard psychiatric treatments. The alternative treatments included medication and various cognitive and behavioral therapies. The predominant trend is clear: only small differences between brief dynamic therapy and other treatments are generally apparent. No individual study effect size was greater than 0.30.

The single comparison (25) of one form of dynamic therapy (Davanloo approach) with another (Pollack and Horner's brief adaptation therapy) yielded no evidence for the superiority of one treatment.

## CONCLUSIONS

### *Meaning of Effect Sizes*

The effect sizes shown by this analysis can be described as large according to Cohen's definition (41). The translation to percentages communicates even more directly the extent to which a patient is much better off receiving dynamic therapy than no treatment. These effects are somewhat larger than the effect size (0.68) presented by Smith and Glass (2) for the general effects of psychotherapy. The heterogeneous treatments and control conditions used by Smith and Glass, however, may account in part for this difference. Alternatively, it is possible that the more recent studies reviewed here, which controlled the delivery of treatment to a greater extent, demonstrated larger changes than did the naturalistic assessments of dynamic therapy in the past.

In addition to Cohen's definitions, the magnitude of the effects of dynamic therapy can be understood through comparison with other types of interventions in medicine. Rosenthal (43) has performed such comparisons using the Smith and Glass meta-analysis (2). He demonstrated that the 0.68 effect size found by Smith and Glass was larger than the effect sizes for several well-known clinical trials in medicine which were halted before completion because it was decided the effect was large enough that it would be unethical to withhold from some patients a clearly efficacious treatment. As mentioned, the effect sizes for dynamic therapy versus waiting list control conditions found here were even larger than the effect size reported by Smith and Glass.

Obviously, with aspects of patient care that involve death or serious illness, even a small treatment effect might be deemed to be especially important. Nevertheless, it is informative to see that the effects of brief dynamic therapy (and psychotherapies in general) are strong in comparison to the effects of such medical treatments.

Other forms of psychotherapy (besides dynamic) were not compared to waiting list control conditions in this investigation. Dobson (5) reported an average effect size of 2.15 (based on Beck Depression Inventory scores) for comparisons of Beck's cognitive therapy to a waiting list or no treatment for depression. Although this value is substantially larger than the effect sizes reported here for comparisons of brief dynamic therapy and waiting list conditions, there is as yet no direct evidence for superiority of cognitive therapy, because the two studies that directly compared a manual-based dynamic or interpersonal therapy to cognitive therapy for the treatment of depression (23, 26) showed no differences between these treatments. It is likely that depression is a condition that responds well to treatments and that this accounts for the large effect size reported by Dobson (5) for comparisons of cognitive therapy to a waiting list and to no treatment.

The data reported here on dynamic therapy's lack of superiority to other standard psychiatric treatments are perhaps not surprising in light of previous reviews of the psychotherapy literature which have shown that various treatments do not differ in their effectiveness (2, 3). The fact that these conclusions hold up in studies where the treatment variable has been standardized and controlled through the use of treatment manuals is, however, still noteworthy. Although this finding appears robust, it is probably unwarranted to generalize this conclusion across all patient populations, outcome measures, and treatment types. For example, brief dynamic therapy has yet to be compared with exposure and response prevention in the treatment of obsessive-compulsive disorder. It is conceivable that, given the documented success of this behavioral treatment, exposure and response prevention would be shown to be superior to dynamic therapy on measures of compulsive behaviors. In brief, these unresearched questions are still unanswered.

Despite the strong effects in the comparisons of brief dynamic therapy and waiting list control conditions, there was less evidence for brief dynamic therapy's superiority to other treatment conditions that were not standard psychiatric treatments. Some studies, however, did yield evidence of superior efficacy. Moreover, in several studies there were higher dropout rates with the alternative treatments than with dynamic therapy. However, given the variation in the findings and the diverse nature of the control conditions and patient groups, it is difficult to draw meaningful conclusions from this small set of studies. Clearly, more research is needed to assess whether brief dynamic therapy is more beneficial than drug counseling, self-help groups, and the like.

The rigorous requirements (such as careful selection, training, supervision, and monitoring of therapists and the use of treatment manuals) that have been implemented in psychotherapy outcome research and were used as criteria for selection of the studies reviewed here may limit the generalizability of the findings to the outpatient practice of dynamic therapy. On the one hand, the careful selection and supervision of therapists is likely to ensure that a high-quality service is delivered; on the other hand, therapists in practice are not bound by a particular treatment guide or manual. Therapists in practice would therefore have more flexibility in their clinical work, which could conceivably lead to more favorable outcomes. Thus, what is gained in knowledge about the use of specific treatments under controlled conditions might also be a loss in terms of generalizability to the actual current practice of dynamic psychotherapy. Not only were the studies reviewed here performed under highly controlled conditions, but some of the forms of treatment studied may not reflect dynamic therapy as it is typically practiced. Interpersonal therapy (34), for example, was investigated in four of the 11 studies, but this approach may be quite distant from the psychoanalytically oriented forms of dynamic therapy more commonly practiced. This aspect of the data base for this review further limits its generalizability.

### *What Is Missing?*

An examination of what is not contained in this review can help further illuminate its limitations and point the way for future research. Lack of information on certain treatments, patient groups, outcome measures, various treatment lengths, follow-up assessments, and interaction hypotheses will be discussed in turn.

Most notably missing from studies of brief dynamic therapy are evaluations of Sifneos's well-known approach (15). Although two studies comparing this approach to a waiting list control (44, 45) and a study involving Sifneos's approach and two other brief dynamic therapies (46) have been conducted, data from these studies were not presented in a manner amenable to a meta-analysis. Means and standard deviations (or significance tests) were not presented for these studies, and the types of outcome measures used here were not employed. In addition, two studies (44, 45) used trainees as therapists. These studies, however, are important contributions to the literature on brief dynamic therapy. Unlike many of the studies used for the meta-analysis reported here, these three studies of Sifneos's approach involved patients who were carefully selected on the basis of explicit criteria for short-term dynamic therapy. Also, the investigators in these studies attempted to operationalize psychodynamic change, rather than examining only symptomatic change. All three studies showed considerable positive evidence for the effectiveness of Sifneos's approach. More research is needed to document the size of the effect on different forms of outcome.

Another limitation of the studies I have reviewed is that many of the patient groups were types that clinicians believe are particularly difficult to treat. Included were two studies of opiate addicts (24, 30), one of cocaine abusers (29), and one of patients with personality disorders (25). Although brief dynamic therapy may be most indicated for adjustment disorders, some anxiety disorders, and relationship conflicts, studies focusing on these problems have not been performed, with the exception of one study on posttraumatic stress disorder (27). A larger effect size for brief dynamic therapy might be expected if these "ideal" patient types were chosen for research.

The outcome measures of target symptoms, general symptoms (SCL-90), and social adjustment (Social Adjustment Scale) were selected because these measures are commonly used and it is preferable to calculate effect sizes within outcome domains rather than combining results across domains and measures. These measures, however, do not capture the specific areas where short-term dynamic therapy theoretically should be most successful. Studies of more theoretically relevant measures—dynamic conflicts, transference themes, and relationship patterns (e.g., 47)—are beginning to appear, but these measures have not yet been used in efficacy studies. With the exception of Klerman's interpersonal therapy, which focuses on manifest social adjustment, the other brief dynamic therapies were evaluated in terms of outcome measures that were not the central focus of treatment. Therapies such as medication, cognitive therapy, and behavioral treatments, which do focus directly on overt symptoms, might be expected to achieve larger changes on these measures. Larger effects for brief dynamic therapy may be evident once theoretically relevant measures are studied. Although previous research has often failed to detect specificity of the effects of different treatments in theoretically important outcome domains, the lack of such findings is likely to be a function of the difficulty in measuring these domains.

In searching for changes in measures that are theoretically important for brief dynamic therapy, it is essential that patients receive an adequate "dose" of treatment. Howard et al. (48) pooled data from many studies of eclectic therapy to determine the relationship between "dose" of psychotherapy and symptomatic outcome. Their results indicated that 75% of patients achieve an effective "dose" of therapy (i.e., symptom relief) within 26 sessions. In psychodynamic therapy, important therapeutic work (the working through process) is likely to take place after the initial symptom relief, and an adequate period for such working through is probably necessary for dynamic change to occur. Thus, studies designed to test the efficacy of dynamic therapy should not only measure the theoretically important variables but should also allow enough time for change in these variables to occur.

It may not be necessary, of course, for the working through to occur only during psychotherapy sessions. A very brief (12-session) dynamic therapy might begin the working through, and then the successful patient might be able to continue the process after the termination of treatment (18). Research on this process would have to include assessment of therapeutic benefits some time after the treatment formally ends. As mentioned earlier, few follow-up results are available. Ideally, the follow-up period should be free of further treatment, since this additional treatment would confound interpretation of the benefits apparent at the follow-up assessment. No studies performed to date have attempted to control the follow-up period. With patients in need of further treatment, however, the ethical problems of withholding treatment would have to be considered.

A final issue not taken up by this review is the role of other factors that might moderate the relationship between treatment type and outcome. Investigators would do well to look for interactions between patient characteristics and treatment types in evaluating efficacy data. The study by Piper et al. (22) on changes associated with dynamic therapy and a waiting list control condition for patients with high and low "quality of object relations" is an excellent example of the examination of interactions. To a certain extent this issue reduces to the problem discussed earlier, defining the appropriate patient group for dynamic therapy. It is unlikely, however, that only patients who seem theoretically suitable for dynamic therapy will be selected in future studies, especially considering the current diagnostic emphasis in psychiatry and the resulting constraints on federally funded research. Rather than select patients on the basis of suitability for dynamic therapy, researchers are more likely to measure variations in patient characteristics and relate these variables to outcome within and across treatment modalities.

The construct of "suitability for dynamic therapy" itself needs further research. Although there are clinical indicators of this quality, no reliable and valid assessment device has yet been created that can be used to test these clinical hypotheses. Actually, it may be of interest to ask not only what types of patients are in general suitable for dynamic therapy but also what types of patients do best and worst in brief dynamic therapy compared to an alternative therapy. For example, when one compares the process of dynamic therapy and cognitive therapy, a hypothesis that comes to mind is that patients who have more interest in examining the subtle, complex meanings of events and interpersonal transactions are a better match (and therefore would have better outcomes) with dynamic therapy and that patients who are more task oriented and see things in a more cut-and-dried fashion would probably prefer a straightforward, logical therapy, such as cognitive therapy, which gives a clear, direct explanation of their problems and proceeds in steps with regular homework assignments. By asking these more and more refined questions, researchers stand a better chance of uncovering the conditions under which dynamic therapies and other therapies are most effective.

# Is Sleep Deprivation Useful in the Treatment of Depression?

Ellen Leibenluft, M.D., and Thomas A. Wehr, M.D.

*Objective: The authors critically reviewed the literature on clinical applications of sleep deprivation in the treatment of depression. Data Collection: They included all studies using sleep deprivation for clinical purposes, with the exception of treatment studies that did not provide follow-up beyond a night of recovery sleep. They focused on six uses of sleep deprivation: 1) to potentiate response to antidepressant medication (13 studies), 2) to hasten the onset of action of antidepressant medication or lithium (five studies), 3) to prevent recurrent mood cycles (four studies), 4) as an alternative to antidepressant medication (five studies), 5) as a diagnostic probe (two studies), and 6) to predict response to antidepressant medication (nine studies). Findings: Although the literature appears to demonstrate the efficacy of sleep deprivation as a potentiation strategy, these treatment studies have substantial methodological shortcomings. Well-designed pilot studies indicate that sleep deprivation may hasten the onset of action of thymoleptic medications. Sleep deprivation may prevent premenstrual mood swings, and response to sleep deprivation may differentiate depressive pseudodementia from primary degenerative dementia with depression. Studies attempting to use sleep deprivation to predict response to antidepressant medication have yielded inconsistent results. Conclusions: Given the noninvasive nature of sleep deprivation, it would be useful to determine if even a small subset of refractory patients respond to it. The authors suggest future research directions to determine the usefulness of this potential treatment.*

(Am J Psychiatry 1992; 149:159–168)

Approximately 60 studies involving more than 1,700 patients (1) have described the antidepressant efficacy of sleep deprivation. The average response rate to a single night of sleep deprivation reported in such studies was nearly 60% (2). Sleep deprivation is an attractive antidepressant treatment because it acts rapidly and is noninvasive, inexpensive, and well tolerated by most patients. However, sleep deprivation usually precipitates only a transient antidepressant response. Wu and Bunney (1) reported that 83% of unmedicated patients and 59% of medicated patients relapsed after a night of recovery sleep. Furthermore, a patient's response to one night of sleep deprivation may not accurately predict his or her response to repeated treatments (3–7). Therefore, the clinical utility of sleep deprivation remains unclear.

Two articles (1, 2) have reviewed the phenomenology as well as possible underlying mechanisms of the response to sleep deprivation. However, these reviews did not focus on the clinical utility of sleep deprivation in the diagnosis and treatment of mood disorders. In this review, we will describe six possible clinical applications of sleep deprivation and discuss the published studies testing the efficacy of each application. Thus, we will summarize the current state of sleep deprivation research in terms of its relevance to patient care.

The possible clinical applications of sleep deprivation in mood disorders are listed in appendix 1. Four of these applications use sleep deprivation to treat depression, and the remaining two use response to sleep deprivation as a diagnostic aid or a prognostic tool. Since the relapse rate in unmedicated patients is high, the first three clinical applications use sleep deprivation in combination with antidepressant medication. In the first and most widely tested clinical application, sleep deprivation is used to potentiate a patient's response to antidepressant medication. Second, sleep deprivation has been combined with antidepressants or lithium at the beginning of treatment in an attempt to hasten the onset of action of the medication. Third, either alone or in combination with antidepressants, sleep deprivation may be useful in preventing recurrent mood cycles. Fourth, sleep deprivation alone has been used to treat unmedicated patients.

Thus, the first four clinical applications use sleep deprivation as an antidepressant treatment or as an adjunct to other thymoleptic treatments. The final two clinical

applications attempt to use response to sleep deprivation as a diagnostic marker and a predictor of response to somatic treatments. For example, response to sleep deprivation has been used to differentiate dementia from depression in geriatric patients and to predict a patient's subsequent response to antidepressant medication in general or to a particular class of antidepressants.

A 1-day response to sleep deprivation is too transient to be clinically useful. Therefore, we included in our review only those treatment studies which included follow-up beyond a night of recovery sleep.

## USING SLEEP DEPRIVATION TO POTENTIATE RESPONSE TO ANTIDEPRESSANT MEDICATION

In 13 studies, chronically depressed patients receiving medication have been deprived of sleep in an attempt to improve their clinical status (table 1). The studies described in table 1 vary greatly in all aspects of their design, such as inclusion criteria, schedule of sleep deprivation treatments, duration of follow-up, and response criteria. These differences in design make comparisons across studies difficult.

Most of the investigators studied heterogeneous groups of depressed subjects. Thus, the study groups included patients with endogenous, reactive, unipolar, bipolar, secondary, and schizoaffective depression. All of the studies listed in table 1 used adult patients; however, King et al. (22) described a 12-year-old boy receiving imipramine whose clinical status improved with the addition of sleep deprivation and lithium carbonate. None of the studies used standardized diagnostic interviews to classify patients. Dessauer et al. (18) were the only investigators who attempted to define a treatment-resistant sample on the basis of the number and duration of previous depressive episodes. No study examined treatment-resistant patients who were selected on the basis of number and type of previous antidepressant (or ECT) treatments. Although a number of investigators noted that their patients had not responded to previous trials of antidepressants, the nature and duration of these trials were not usually specified (9–11). In table 1 we included only those patients who were noted to be receiving "chronic" antidepressants, or, if the duration of treatment was specified, those patients who had been receiving medication for at least 3 weeks.

With three exceptions (17, 18, 20), these treatment potentiation studies used total sleep deprivation—keeping the patient awake for a 36-hour period. However, the frequency and total number of treatments varied from study to study and from patient to patient within the same study. In many studies, patients were treated with sleep deprivation once or twice a week until they responded or until a predetermined maximum number of treatments was reached. Using this approach in a

**TABLE 1 (continued)**

| Response Criterion[b] | Type of Depression | Number of Subjects | Responders | |

| 50% | Mixed | 17 | 10 | 59 |
| | | 411 | 170 | 41 |

sample of elderly patients, Cole and Müller (10) found that responders required a mean of 3.3 treatments, but von Scheyen's mixed-age sample (14) required a mean of five treatments. Some studies (8, 9, 11) did not specify the frequency or total number of treatments.

There is evidence (23–26) that partial sleep deprivation, where the patient is kept awake for only part of the night, may be as effective as total sleep deprivation. Specifically, late partial sleep deprivation, where the patient is awakened at about 2:00 a.m. and kept awake until 10:00 p.m., appears to be as effective as total sleep deprivation and more effective than early partial sleep deprivation. In early partial sleep deprivation, the patient is kept awake until 2:00 a.m., allowed to sleep from 2:00 a.m. to 7:00 a.m., and then kept awake until 10:00 p.m. Obviously, partial sleep deprivation produces less fatigue than total sleep deprivation and thus has advantages as a clinical intervention. Therefore, several groups have attempted to use late partial sleep deprivation to potentiate response to antidepressant medication. For example, Dessauer et al. (18) administered late partial sleep deprivation once every 5 days for a total of five treatments, and Holsboer-Trachsler et al. (20, 21) administered late partial sleep deprivation three times in a week. As can be seen in table 1, their response rates were comparable to those of the other studies.

However, it is difficult to compare response rates across studies, since the time point at which response was determined varied from 2 days (8, 17) to 3–12 months (16) after recovery sleep. Furthermore, each study used different outcome measures, and studies differed in the percent of improvement that was considered a clinical response. For example, Cole and Müller (10) required a 30% decrease in Hamilton Rating Scale for Depression score as a response criterion, but Holsboer-Trachsler et al. (20, 21) required a 50% decrease. Many of the studies specified the rating scale used but not the degree of change used to define a favorable response (9, 11–18). In all of the studies, both patients and raters were aware of the patient's sleep schedule and the purpose of the study.

The failure to use blind raters and to control for patient expectations are serious methodological shortcomings. Furthermore, only one study (18) included a comparison group. It is difficult to design a comparison or control group for sleep deprivation because patients must be aware of the fact that they are being deprived of sleep. This has been a major criticism of the sleep deprivation literature, and Milstein et al. (27) have argued that the reported response to sleep deprivation is in fact a placebo response. Dessauer et al. (18) created a comparison group by dividing patients into those with poor prognoses and those with good prognoses on the basis of the number and duration of their previous depressive episodes. Fourteen good-prognosis patients received medication alone, and 18 poor-prognosis patients received both medication and five late partial sleep deprivation treatments at 5-day intervals. At the end of 25 days, both groups had comparable outcomes. Dessauer et al. maintained that sleep deprivation was effective in potentiating the antidepressant medication because the outcome of the poor-prognosis group was better than expected, equaling that of the good-prognosis group. Of course, this conclusion can be challenged because neither patients nor raters were blind to the hypothesis of the study and because raters were aware of the patient assignments. Furthermore, the categorization of the poor-prognosis group may have been faulty, and it is unclear if their better-than-expected outcome was in fact due to the sleep deprivation.

Taken together, these studies represent a total of 411 patients whose antidepressant treatment was supplemented by sleep deprivation. Overall, the studies reported a response rate of 41%. Given the refractory nature of the patients' illnesses and the fact that sleep deprivation is a benign and simple procedure, this response rate can be viewed as encouraging. If one-third of treatment-resistant patients can be helped by adding sleep deprivation to their medication regimen, then sleep deprivation would certainly have an important role in the treatment of depressed patients. However, these studies can be criticized because of their methodological shortcomings. Therefore, although these initial results are promising, it is clear that the capacity of sleep deprivation to potentiate antidepressant medication warrants further study under more carefully controlled conditions.

**TABLE 2. Studies Using Sleep Deprivation to Hasten Onset of Action of Antidepressant Medication or Lithium**

| Author | Year | Treatment Group and Schedule[a] | Blind Raters | Duration of Study (days) | Result |
|---|---|---|---|---|---|
| Loosen et al. (28) | 1976 | Clomipramine plus total sleep deprivation (N=8): sleep deprivation on night 0, medication starts day 1<br>Clomipramine (N=8): medication starts day 1 | No | 10 | Clomipramine plus total sleep deprivation superior until day 10; significant difference on days 1–3 |
| Elsenga and van den Hoofdakker (29) | 1980 | Clomipramine plus total sleep deprivation (N=9): medication starts day 1, sleep deprivation on nights 1, 3, 8, 10<br>Placebo plus total sleep deprivation (N=9): placebo starts day 1, sleep deprivation on nights 1, 3, 8, 10<br>Clomipramine (N=9): medication starts day 1 | Yes | 15 | Clomipramine plus total sleep deprivation superior over 15 days according to self-ratings but not blind ratings |
| van Bemmel and van den Hoofdakker (30) | 1981 | Clomipramine plus sleep deprivation I: medication starts day 1, total sleep deprivation on nights 1, 3, 8; 2 hours of sleep on night 4 and 5 hours of sleep on night 9<br>Clomipramine plus sleep deprivation II: medication starts day 1, total sleep deprivation on nights 1, 3, 8; 5 hours of sleep on night 4 and 2 hours of sleep on night 9 | No | 10 | Both groups had better response on days 5–10 than groups studied in 1982/1983 (31) |
| Elsenga and van den Hoofdakker (31) | 1982/ 1983 | Clomipramine plus total sleep deprivation (N=10): medication starts day 1, sleep deprivation on nights 1, 3, 8, 10<br>Placebo plus sleep deprivation (N=10): placebo starts day 1, sleep deprivation on nights 1, 3, 8, 10<br>Clomipramine (N=10): medication starts day 1 | Yes | 15 | Clomipramine plus sleep deprivation group had lowest Hamilton rating after 1 week |

[b] Medication was double-blind.

## USING SLEEP DEPRIVATION TO HASTEN THE ONSET OF ACTION OF ANTIDEPRESSANT MEDICATION OR LITHIUM

Five controlled studies have attempted to use sleep deprivation to hasten the onset of action of antidepressant medication or lithium during the initial phase of treatment (table 2). These studies can also be viewed as attempts to prolong the antidepressant effect of sleep deprivation by combining it with medication. In either case, the goal is to achieve a more rapid antidepressant response than occurs with the use of medication alone. Compared with the studies using sleep deprivation as a potentiation strategy, the patient samples in these studies were smaller. However, each study had one or more control groups, and several used blind raters.

In 1978, Philipp (26) suggested that concurrent use of antidepressant medication could prolong the effect of a night of sleep deprivation and presented uncontrolled data to support this contention. Loosen et al. (28) were the first to compare systematically a group of patients receiving medication (clomipramine) with a group receiving medication plus sleep deprivation. The group receiving medication plus sleep deprivation received total sleep deprivation the night before the first dose of medication. The sleep deprivation patients had a superior outcome for the first 10 days of treatment, although the difference was statistically significant only for the first 3 days. Although ratings were done by two independent raters, the investigators did not note whether the raters were aware of patient assignments.

Elsenga and van den Hoofdakker (29, 31) and van Bemmel and van den Hoofdakker (30) also published a series of studies combining sleep deprivation with clomipramine. In these studies, patients treated with clomipramine and sleep deprivation were compared with a group receiving sleep deprivation and placebo and with a group receiving clomipramine alone. Patients in the clomipramine/sleep deprivation group and in the placebo/sleep deprivation group underwent 2 nights of total sleep deprivation a week for 2 successive weeks. Patients in the clomipramine/sleep deprivation group started taking clomipramine the night before the first sleep deprivation. In the first of these studies (29), self-ratings, but not blind ratings, showed that clomipramine/sleep deprivation was superior over the experimental period of 15 days. In a later study (31), the clomipramine/sleep deprivation group had lower scores on the Hamilton depression scale than the other groups at the end of the first week. However, by the end of 15 days, the Hamilton depression scores of the clomipramine/sleep deprivation group and the clomipramine group were comparable. The pilot data of van Bemmel and van den Hoofdakker (30) indicated that the ratings of the clomipramine/sleep deprivation group were further improved by limiting patients' sleep to 2 or 5 hours on the night after total sleep deprivation.

Baxter et al. (32, 33) hypothesized that the mood-stabilizing properties of lithium might be useful in preventing relapse after recovery sleep. In a pilot study, they selected patients with unipolar and bipolar depression who had previously demonstrated a positive response to partial sleep deprivation. Patients were randomly assigned to treatment with late partial sleep deprivation and lithium, late partial sleep deprivation and placebo, or lithium alone. On day 1 of the study, patients in the lithium treatment groups were given a loading dose that was calculated to yield a serum lithium level of 1.0 meq/liter that day. Late partial sleep deprivation was carried out on days 1 and 2. On day 5, patients in the late partial sleep deprivation/lithium group had significantly lower Hamilton depression scores than patients in the other two groups. Five patients who were crossed over from the late partial sleep deprivation/lithium group or the late partial sleep deprivation/placebo group to the other pill had superior results in the late partial sleep deprivation/lithium condition. Throughout the study, raters were blind to medication but not to late partial sleep deprivation.

These studies indicate that several nights of total sleep deprivation or late partial sleep deprivation, administered early in the course of treatment with clomipramine or lithium, may yield a faster antidepressant response than drug treatment alone. If this application of sleep deprivation proves to be effective in larger samples of patients, it would have substantial clinical utility. For example, it may be possible to decrease the period during which a patient poses a high suicide risk or to shorten the inpatient stay of patients whose clinical status requires that they be hospitalized until antidepressant medication takes effect. Thus, like ECT, sleep deprivation may have a role in inducing more rapid remission than other available treatments. Although sleep deprivation is unlikely to have as dramatic or predictable effects as ECT, it is also a considerably more benign intervention. Therefore, this application of sleep deprivation clearly warrants further study using larger samples, control groups, and blind raters.

## USING SLEEP DEPRIVATION TO PREVENT RECURRENT MOOD CYCLES

Several groups have attempted to use sleep deprivation to prevent mood cycles in patients with rapid-cycling disorder. Papadimitriou and Christodoulou (34) reported nine drug-free patients with rapid-cycling disorder (five bipolar, four unipolar) who were placed on a regimen of weekly total sleep deprivation in an attempt to prevent their depressive cycles. All of the patients had undergone numerous unsuccessful trials of antidepressants, and some had received ECT. In five of the nine patients, prophylactic sleep deprivation appeared to result in fewer depressive episodes and more periods of euthymia than the patients experienced at baseline. However, since antidepressant medication can induce or exacerbate rapid cycling (35), it is possible that the reduction in the patients' cycling was caused by the discontinuation of antidepressant medication. Furthermore, since sleep deprivation has been reported to precipitate mania in some patients with bipolar disorder (8, 36–38), it is surprising that none of the patients of Papadimitriou and Christodoulou (34) became manic in response to the sleep deprivation.

Kjellman et al. (39) reported two drug-free patients with unipolar depression whose cycles were prevented by regular sleep deprivation. Lovett Doust and Christie (40) described a patient with bipolar disorder taking clomipramine, lithium carbonate, and methotrimeprazine who deprived herself of sleep when she began to feel depressed. The patient kept herself awake for 5 nights over a period of 9 months and had substantially less depression and hypomania during that period than she had had during the preceding 9 months. These anecdotal reports indicate that prophylactic sleep deprivation, either alone or in combination with medication, may be useful for some patients with rapid-cycling mood disorder. However, the risk of precipitating mania would appear to be substantial in this population (41).

Parry and Wehr (42) reported a pilot study using total sleep deprivation in 10 patients with premenstrual syndrome. The patients were admitted to the hospital for a night of total sleep deprivation when their Hamilton depression scores reached 10 during the premenstrual phase of their cycle. Eight of the 10 patients responded with a decrease of at least 5 points on the Hamilton depression scale. When five of the responders were then entered into a random-order crossover comparison of late partial sleep deprivation and early partial sleep deprivation, late partial sleep deprivation was shown to be the superior treatment. Sleep deprivation would be an appealing treatment for premenstrual syndrome—patients who were symptomatic for less than 10 days of the month could avoid having to take medication throughout their entire cycle. Therefore, a larger trial of sleep deprivation in premenstrual syndrome would be worthwhile.

## USING SLEEP DEPRIVATION AS AN ALTERNATIVE TO ANTIDEPRESSANT MEDICATION

Although 60% of drug-free patients had an antidepressant response to a night of sleep deprivation, 83% of them relapsed after a night of recovery sleep (1). Therefore, it is unclear whether sleep deprivation alone would be a viable treatment for acutely depressed patients. In a study providing unusually lengthy follow-up, Kvist and Kirkegaard (43) used 2 or 3 nights of total sleep deprivation as the only treatment in 28 patients with endogenous depression. Eight patients went into complete remission, but five of these responders relapsed within an average of 4 weeks. There was no comparison group, and raters were aware of the patients' sleep schedules.

Manthey et al. (44) treated six drug-free patients with late partial sleep deprivation twice a week for 3 weeks and noted a trend toward improvement. Papadimitriou and Christodoulou (34) treated 19 drug-free patients with total sleep deprivation twice a week for 4 weeks, followed by a maintenance program of weekly total sleep deprivation. Eight of the patients responded to the initial course, and four of the six patients who entered the prophylactic program were noted to have an "excellent response." However, the duration of the follow-up and the response criteria in this study were not clear. Uhde et al. (45) attempted to treat two drug-free bipolar disorder patients with sleep deprivation but found that its efficacy decreased with each successive treatment.

Vogel et al. (46) conducted a double-blind, crossover test of the hypothesis that 3 weeks of REM sleep deprivation would be an effective treatment for depression. Patients receiving REM sleep deprivation were awakened whenever they entered REM sleep, and patients in the control condition were awakened from non-REM sleep. Seventeen of 34 drug-free patients with endogenous depression responded to REM deprivation, and 14 of them stayed in remission for more than 6 months. Although Vogel's results are promising, REM sleep deprivation is a cumbersome procedure that requires continuous EEG monitoring. This has precluded replication of the experiment and would probably limit the clinical applicability of REM sleep deprivation.

The transient and unpredictable nature of the response to sleep deprivation means that sleep deprivation alone is unlikely to be an effective treatment for many depressed patients. However, patients who are unable to tolerate antidepressant medication, either because of side effects or medical contraindications, present the clinician with a difficult challenge. An initial course of sleep deprivation, followed by weekly maintenance treatment, may be a viable treatment option for some of these patients. However, the efficacy of sleep deprivation alone has not been tested in patients who are either treatment refractory or unable to tolerate medication.

## USING SLEEP DEPRIVATION AS A DIAGNOSTIC AID

When an elderly patient has depressive symptoms and cognitive impairment, the clinician may be hard pressed to distinguish depressive pseudodementia from primary degenerative dementia with depression. It is important to differentiate the two disorders because they have different treatments and prognoses. In 1986, Letemendia et al. (47) reported four depressed, confused patients who responded to a night of total sleep deprivation. While the patients were in the euthymic state induced by total sleep deprivation, their cognitive function was assessed and the diagnosis of dementia was ruled out.

In a related study, Buysse et al. (48) tested whether a positive response to sleep deprivation had diagnostic value in patients with symptoms of both depression and dementia. They found that a positive response to sleep deprivation distinguished patients with depressive pseudodementia from those with primary degenerative dementia with depression in a study group of 26 patients. Given the high prevalence of both organic and depressive symptoms in the elderly and the noninvasive nature of sleep deprivation, this application could have substantial clinical utility.

## USING SLEEP DEPRIVATION TO PREDICT RESPONSE TO ANTIDEPRESSANT MEDICATION OR ECT

In 1976, Wirz-Justice et al. (49) suggested that patients who felt less depressed the morning after sleep deprivation (day-1 responders) were likely to respond to an antidepressant that inhibits serotonin uptake, such as clomipramine. In addition, they suggested that patients who felt less depressed on the day after recovery sleep (day-2 responders), who represent 10% of the responders to sleep deprivation, would respond preferentially to an antidepressant that inhibits noradrenergic uptake, such as maprotiline. Wirz-Justice et al. presented pilot data from an open study to support this hypothesis (table 3).

Eight other studies have also addressed the question of whether response to sleep deprivation can predict response to antidepressant medication in general or to a particular class of antidepressants (table 3). In a follow-up to their original report, Wirz-Justice et al. (52) found that a response to total sleep deprivation on day 1 or day 2 predicted a good response to antidepressants in general, although total sleep deprivation response did not predict response to a particular class of antidepressants. In contrast, both Höchli et al. (54) and Reimann and Berger (55) found that a positive response to total sleep deprivation response predicted a negative response to clomipramine, and Amin (50) reported that total sleep deprivation response had no predictive value. Further complicating the situation, Fahndrich (53) studied a relatively large sample of patients and concluded that a positive response to total sleep deprivation predicted a positive response to clomipramine and a negative response to total sleep deprivation predicted a positive response to maprotiline.

The open design of these studies may account for their contradictory results. Two other studies have used a double-blind design to study the prognostic value of sleep deprivation. Roy-Byrne et al. (4) reported that a positive response to total sleep deprivation predicted a positive response to carbamazepine, and Kasper et al. (56), in a double-blind study confirming the original report of Wirz-Justice et al. (49), found that day-2 re-

TABLE 3. Studies Using Sleep Deprivation to Predict Response to Antidepressant Medication

| Author | Year | Number of Subjects | Medication | Duration of Treatment (days) | Rating Scale | Response Criterion | Result |
|---|---|---|---|---|---|---|---|
| Wirz-Justice et al. (49) | 1976 | Not stated | Clomipramine, maprotiline | Not stated | Not stated | Not stated | Positive day-1 response to total sleep deprivation[a] predicted positive clomipramine response; positive day-2 response to total sleep deprivation predicted positive response to maprotiline |
| Amin (50) | 1978 | 22 | Maprotiline, viloxazine, imipramine | 28 | Hamilton scale | 30% decrease in score | Total sleep deprivation had no predictive value |
| Philipp and Werner (51) | 1979 | 15 | Lofepramine | 21 | Hamilton scale | 35% decrease in score | Positive response to late partial sleep deprivation[b] predicted positive response to lofepramine |
| Wirz-Justice et al. (52) | 1979 | 52 | Maprotiline, clomipramine, imipramine | Not stated | Hamilton scale | 33% decrease in score for sleep deprivation, hospital discharge for drug response | Positive response to total sleep deprivation predicted positive general but not specific drug response |
| Fahndrich (53) | 1983 | 60 | Intravenous clomipramine, intravenous maprotiline | 21 | Global self-assessment, Hamilton scale | Positive change in global score for sleep deprivation, 50% decrease in Hamilton score for drug response | Positive response to total sleep deprivation predicted positive response to clomipramine; negative response to total sleep deprivation predicted positive response to maprotiline |
| Roy-Byrne et al. (4)[c] | 1984 | 16 | Carbamazepine | 28–63 | Bunney-Hamburg scale | 2-point decrease in score | Positive response to total sleep deprivation predicted positive response to carbamazepine |
| Höchli et al. (54) | 1986 | 10 | Clomipramine | 18 | Hamilton scale, adjective checklist | 30% decrease in score | Positive response to total sleep deprivation predicted negative response to clomipramine |
| Riemann and Berger (55) | 1990 | 17 | Clomipramine | 19 | Hamilton scale | 30% decrease in score | Positive response to total sleep deprivation predicted negative response to clomipramine |
| Kasper et al. (56)[c] | 1990 | 42 | Fluvoxamine, maprotiline | 28 | Hamilton scale | 30% decrease in score | Positive day-2 response to total sleep deprivation predicted positive response to maprotiline |

[a] In total sleep deprivation, patient stays awake for 36 hours.
[b] In late partial sleep deprivation, patient stays awake from 2:00 a.m. until 10:00 p.m.
[c] Double-blind study.

sponders were more likely to respond to maprotiline than to the serotonin uptake inhibitor fluvoxamine.

It is conceivable that more double-blind studies would yield consistent results concerning the utility of total sleep deprivation as a predictor of response to antidepressant treatment. However, given their contradictory results, the existing studies do not clearly indicate a role for sleep deprivation in the prediction of antidepressant response.

## CONCLUSIONS

Depressed patients, who frequently complain of insomnia, react with surprise to the notion that staying awake at night may be a useful treatment for their depression. Clinicians, too, often respond with skepticism to the idea of using sleep deprivation as an antidepressant. This skepticism is well-founded, given the fact that the sleep deprivation literature is largely uncontrolled. Furthermore, the transient and somewhat unpredictable nature of the response to sleep deprivation makes it unlikely that it will be an effective treatment for the vast majority of unmedicated patients. However, our review indicates that several clinical applications of sleep deprivation bear further study under controlled conditions.

There is evidence from uncontrolled studies that sleep deprivation can potentiate the medication response of patients who have achieved a partial remission. Even well-controlled studies may be unable to demonstrate an overall effect in a sample of treatment-refractory patients because such a sample is likely to consist of a heterogeneous group of depressed patients. However, given the noninvasive nature of sleep deprivation, it would be useful to determine if even a small subset of refractory patients respond to sleep deprivation. If this responsive subset exists, and if the response lasts for approximately a week, then weekly sleep deprivation could be a useful adjunct to ongoing pharmacotherapy for some patients.

To define a subgroup of sleep-sensitive depressed subjects, it is necessary to identify reliable predictors of response to sleep deprivation. Several variables, including age, sex, and diagnosis, do not appear to be correlated with response to sleep deprivation (57). However, two possible predictors of response to sleep deprivation have been described. First, the presence of diurnal variation may predict a positive response to sleep deprivation (58–60). Patients with typical diurnal variation experience a gradual improvement in mood as the day wears on, and van den Hoofdakker (61) has suggested that sleep deprivation acts as an antidepressant because it allows this natural remission to continue, uninterrupted by sleep. Second, high nocturnal minimum rectal temperature during sleep deprivation may be associated with a positive clinical response (62; unpublished data of T.A.W.). If future studies confirm the reliability of these predictors, it may become easier to identify those refractory patients who would benefit from a trial of adjunctive sleep deprivation.

Even if a given patient responds to a single night of sleep deprivation, his or her response to subsequent sleep deprivation trials is unclear. There are reports that patients who respond to sleep deprivation do not do so predictably from night to night (3–7). Roy-Byrne et al. (4) suggested that patients develop tolerance to sleep deprivation, and Pflug (5) presented preliminary data in support of this contention. However, the data of Elsenga and van den Hoofdakker (63) suggest that the concurrent use of antidepressant medication improves the consistency of the response to sleep deprivation. To date, there has been limited systematic study of the degree to which response to sleep deprivation is replicable. Clearly, such studies would have implications for the utility of sleep deprivation as an adjunct to medication.

In addition to its use as a potentiation strategy, other applications of sleep deprivation that may hold particular promise include its use in hastening the onset of action of antidepressants, in treating late luteal phase dysphoric disorder, and in differentiating depressive pseudodementia from primary degenerative dementia with depression. Preliminary studies in each of these areas have had encouraging results. These studies have included appropriate control groups, but the sample sizes have been small and the results have not yet been replicated at different centers.

Clinicians frequently question whether outpatient sleep deprivation is a practical treatment. Specifically, they wonder whether depressed patients will have sufficient motivation to spend all or part of a night awake, as prescribed. To overcome this problem, several treatment centers in Europe have established weekly sleep deprivation clinics for patients who have suboptimal medication responses. Patients who have difficulty depriving themselves of sleep at home attend the overnight sleep deprivation clinic and stay awake in the company of a nurse or technician and other patients (personal communication from S. Kasper). In a controlled trial that we are conducting, using sleep deprivation to potentiate antidepressant medication, patients are admitted to an inpatient unit the evening before sleep deprivation and discharged the following morning. Further clinical experience with sleep deprivation will clarify whether such supervised clinics or brief hospitalizations are necessary to deprive patients of sleep or whether patients can successfully deprive themselves at home.

Future research will determine whether, and in which clinical situations, sleep deprivation is a practical and effective antidepressant treatment. Furthermore, sleep deprivation research contributes to a general understanding of the pathogenesis and treatment of mood disorders, since sleep deprivation may share a mechanism of action with other, more commonly used antidepressant treatments. For example, both tricyclic antidepressants (64, 65) and monoamine oxidase inhibitors (66, 67) suppress REM sleep, and Vogel (68) has argued that this property accounts for their therapeutic efficacy. In addition, sleep deprivation appears to augment a nocturnal surge of thyrotropin (37, 69) and elevate $T_3$ levels (70, 71) in normal individuals as well as in patients with unipolar and bipolar depression. This finding suggests that a trial of sleep deprivation may be a form of thyroid potentiation where the thyroid hormone comes from an endogenous source. The rapidity of the response to sleep deprivation may provide a relatively accessible means of probing the neurobiology of antidepressant therapies. In this way, research concerning the efficacy and mechanism of sleep deprivation's antidepressant properties may yield not only new therapeutic techniques but also an increased understanding of the biological mechanisms underlying affective illnesses and their treatment.

# Assessing Competency to Make a Will

James E. Spar, M.D., and Andrew S. Garb, J.D.

*The finding by a court that the author of a will (the testator) lacked mental capacity or was subject to undue influence at the time the will was executed can invalidate the will. A psychiatrist may be asked to assess the competency of a testator when he or she is planning to create or modify a will or after the death of a testator when the will is challenged. To provide guidelines for such evaluations, the authors reviewed the relevant psychiatric, forensic, and legal literature and drew on their own professional experience as well. They outline a systematic approach to the contemporaneous and retrospective evaluation of the elements that affect decisions about mental capacity and undue influence and offer suggestions for the organization and presentation of expert testimony. Awareness of the relevant legal principles and a systematic clinical approach to the assessment can maximize the quality of the psychiatric consultation and expert testimony.*

(Am J Psychiatry 1992; 149:169–174)

The next few decades are likely to bring an increasing call for psychiatric consultation and expert testimony in cases in which the validity of a will has been, or is expected to be, contested on grounds related to the alleged mental incapacity or susceptibility to undue influence of the will's author (the testator). The factor expected to contribute most to this increase is the growing number of Americans who are living through the age of risk for dementing illnesses, such as Alzheimer's disease, that can produce mental changes likely to raise the legal issues we describe in this article. Other factors include increasing public and professional awareness of these conditions and their mental consequences, increasing receptivity by the courts to evidence regarding mental state, and more permissive rules of evidence pertaining to expert testimony on these issues (1).

Despite a growing literature on mental competency and advances in our understanding of and ability to quantify the cognitive and behavioral consequences of late-life mental illness, there are no published guidelines for conducting a psychiatric consultation or giving expert testimony in cases in which mental incompetence or susceptibility to undue influence is, or could be, the basis for contesting a will. This article reviews the relevant legal issues from a contemporary psychiatric perspective and proposes general guidelines for expert consultation and testimony, illustrated by case material drawn from our experience. The aim of these guidelines is to maximize the quality of testimony, regardless of its position on the issues.

## LEGAL CONCEPTS

While there are several legal grounds upon which the validity of a will or codicil (amendment to an existing will) may be challenged, those with the clearest a priori relation to mental illness are the claim that 1) the testator lacked *testamentary capacity* at the time the disputed will or codicil was signed and 2) that specific contents of the will or codicil resulted from *undue influence* exerted upon the testator by one or more persons. Often both allegations are made simultaneously. If lack of testamentary capacity is proven, the entire will or codicil is invalid; if undue influence is proven, those portions of the will or codicil that either result from or cannot be separated from the results of influence are invalid (2).

### *Testamentary Capacity*

The legal concept of testamentary capacity is generally defined throughout the United States as the testator's having sufficient mental capacity to "understand the nature of the testamentary act, understand and recollect the nature and situation of his or her property, and remember and understand his or her relations to his or her living descendants, spouse, and parents, and those whose interests are affected by the will." Many states further require that "the testator is also free of . . . delusions or hallucinations [which] result in the person's devising his or her

---

Copyright © 1992 American Psychiatric Association.

property in a way which, except for the existence of the delusions or hallucinations, he or she would not have done" (3). Minor variations are found in some states; for example, Massachusetts adds the qualifier "in a general way" to the criterion regarding "the nature and situation of his property" (4). However, a few states require only one of the three criteria; for example, Missouri requires only that the testator have "recognized his obligation to the objects of his bounty and their relation to him" (5), and Minnesota requires only that the testator understand "the nature, situation, and extent of his property" and be "able to hold these things in his mind long enough to form a rational judgement concerning them" (6).

### *Undue Influence*

Undue influence is a more complex and less precisely defined concept. To be considered undue, influence must contain an element of "coercion, compulsion or restraint." Mere appeals or arguments, or influence resulting from gratitude or affection, even if the acts creating these feelings were performed selfishly and were designed to affect the testamentary act, do not constitute undue influence. Rather, the testator's mind must be subjugated to that of another, the testator's free agency destroyed, or the testator's volition overpowered by another. While notions such as "subjugated mind" and "overpowered volition" may resist translation into operational criteria for the psychiatric consultant, some states "presume" the existence of undue influence if certain facts are proved, and they require the accused party (the "influencer") to produce evidence to rebut the charges. These facts are 1) the accused party played an active role in procuring the will, 2) the accused party was in a confidential relationship with the testator (e.g., was a close relative or advisor), and 3) the accused party profited unduly under the provisions of the will. In these states undue influence may be presumed even in the absence of mental illness or infirmity, and psychiatric expert testimony may not be necessary. If any of these three factors do not exist, the burden of proof shifts back to the contestant.

Courts have also identified several "indicia" of undue influence, the existence of which will help establish the contestant's case. Most of these indicia have clear implications for the conduct of the psychiatric consultant. They are 1) unnatural provisions in the will, 2) provisions inconsistent with prior or subsequent expressions of the testator's intentions, 3) a relationship between the testator and the beneficiary that created an opportunity to control the testamentary act, 4) a mental or physical condition of the testator that facilitates the subversion of the testator's free will, 5) the beneficiary's active participation in procuring the will, 6) an undue profit to the beneficiary under the provisions of the will, and 7) a confidential relationship between the testator and the beneficiary. These indicia are applicable in most states, even those that do not recognize presumptive evidence of undue influence.

### *The Role of Mental Illness*

The precise relation between mental illness and testamentary capacity and undue influence is nowhere clearly set forth. Case law seems to hold that mental illness may, but does not necessarily, directly impair testamentary capacity. While the testator must have a "sound mind, or sound mind or memory, or sound and disposing mind and memory" (7), still, "old age or forgetfulness, eccentricities or mental feebleness or confusion at various times of the party making the will are not enough in themselves to warrant holding that the testator lacked testamentary capacity" (8).

Despite these judgments, however, Redmond (1) has made the salient observation that "after a person's death questions are easily raised about his or her competence at a particular point in the past if certain medical conditions have been existing. Medical records and other material such as interviews with family almost always provide some basis for an expert opinion that questions the testamentary capacity of the testator. At the same time there is usually insufficient information and documentation on which the expert witness can formulate an opinion that affirms the testator's testamentary capacity at the time of the will making."

The relation between mental illness and undue influence is, as these indicia imply, somewhat less direct: "It requires much less influence to control the will of a person whose functional abilities have been severely impaired by mental illness or by physical conditions which affect mental functioning . . . . A demonstration of impaired mental powers or a clouding of intelligence of the testator makes it easier to establish a charge of undue influence" (9). Besides mental illness per se, aspects of character and personality that do not imply pathology are also important; for example, it is generally more difficult to establish the existence of undue influence if the testator is intelligent and has a strong and independent character than if the testator is dull and has a more passive, malleable character.

While these remarks apply specifically to wills and codicils, basically the same considerations apply to trusts, which continue to grow in popularity as a means for determining the ultimate distribution of one's assets.

## THE PSYCHIATRIST'S ROLE

Psychiatric consultation may be requested contemporaneously with the signing of a will or codicil or later, at the time the will is challenged. In the first situation, the psychiatrist is usually asked by an attorney retained by the testator, a relative, or the spouse to evaluate the testator before he or she signs a will or codicil and to determine whether the testator has testamentary capacity and is free of undue influence. Either someone has raised the possibility of mental illness or there are circumstances (e.g., the testator intends to leave substantial assets to an unexpected party) that prefigure a subsequent challenge of the will. In the second situation, after a will has been contested, the psychiatrist is usually asked to provide advice about how to attack opposing expert testimony and to examine indirect evidence and render a post hoc opinion regarding testamentary capacity and the operation of undue influence.

## CONTEMPORANEOUS EVALUATION

### *The Testator*

The cornerstone of the contemporaneous evaluation of the testator is the clinical interview. Given that the relevant issue is the testator's mental capacity and freedom from undue influence at the precise moment the testamentary document is executed, this interview should be conducted as close as possible to this moment. The longer the elapsed time between the interview and the moment of execution, the greater the risk of an intervening change in mental status and the less weight may be assigned to the expert's testimony by the trier of fact (i.e., the judge or jury). In order to perform the assessment of capacity, the examiner must first determine from informed, objective sources the nature of the testator's assets and, if possible, the names and relationships to the testator of all potential heirs. If necessary, the latter information can be obtained following the interview. Since consultation is usually requested when those making the request expect a finding that the testator has testamentary capacity and is not under undue influence, the presence of one or two disinterested witnesses during the interview may obviate future allegations that the testator's performance was "coached" or otherwise nonrepresentative. If witnesses are present, the interviewer must ensure that they do not distract or influence the testator, and if there is doubt, the interview should be conducted in private. Because this decision could have an impact on the weight of the interviewer's subsequent testimony, as could other "tactical" decisions such as the use of recording devices (discussed later), such decisions should always be made in consultation with the testator's attorney.

Because true mental capacity is demonstrated only by the testator's best possible performance, every effort should be made to establish rapport, reduce anxiety, and maximize the testator's comfort and cooperation. Although the presence of close family members or friends may help achieve these goals, their possible influence on the testator's performance, or even the appearance of such influence, will generally outweigh the benefits afforded by their presence, particularly in cases where undue influence may be an issue.

The examiner should explain the purpose and nature of the interview and indicate what will be expected of the testator. During the interview the interviewer should attempt to assess the specific legal elements of testamentary capacity, identify any features of the testator's personality and mental status that could affect susceptibility to undue influence, and determine the nature, extent, and general functional consequences of mental illness, if any.

A semistructured interview format is recommended, including a comprehensive mental status examination assessing general appearance, dress, and grooming; orientation; recent and remote memory; attention and concentration; receptive and expressive language and speech function; mood, affect, and psychomotor behavior; thought form, flow, and content; insight and judgment; and higher cognitive functions such as calculations and abstractions. Adjunctive administration of standardized instruments such as the Mini-Mental State examination (10), the Neurobehavioral Cognitive Status Examination (11), and the Hamilton Rating Scale for Depression (12), as appropriate, is also recommended. The interview may be audiotaped or videotaped. If it is, the interviewer should attempt to ensure that recording is not intrusive and does not increase the testator's anxiety and adversely affect his or her performance.

To supplement the clinical interview, information should also be obtained from ancillary sources. With the testator's consent, the spouse, other family members, friends, business associates, personal physicians, and the drafter of the will may be interviewed to gain further information regarding the testator's cognitive functioning and reality testing (which bear on the issue of testamentary capacity) and the testator's personality traits, attitudes, goals, and values (which bear on the issue of undue influence). Since the examiner may not be asked to testify about the evaluation for several years, it is important to record sufficient detail of the assessment to facilitate the examiner's future recollection of events.

### *Testamentary Capacity*

The elements of testamentary capacity may be assessed directly by asking the testator to describe his or her assets in as much detail as possible; to articulate his or her understanding of what a will or codicil is and what it does; and to explain who the people named in it are and how they are related to him or her. Because there is no precise legal definition of the terms "recollect" and "remember," the consultant should assess unassisted recall, prompted recall, and recognition memory. The testator who cannot recall one or more of the elements we have mentioned should be prompted (i.e., given "hints"), the specific content of which should be recorded (e.g., "What about stock in large corporations?"). If the testator cannot recall an element even with hints, he or she should be given the opportunity to demonstrate recognition knowledge by selecting responses from a list that contains the correct items and several feasible but incorrect distracters; for example, "A will is 1) a statement about how you feel about your relatives, 2) instructions for how your property should be distributed after your death, 3) a promise to pay you a certain amount of money if you get hurt, 4) a paper that tells you your bank balance" or "Which things on this list do you own? 1) a house in Westwood, 2) a house in Malibu, 3) an apartment building in Santa Monica." The stimulus lists should be saved for future reference, and responses should be recorded verbatim.

Although recognition knowledge alone is not likely to be accepted as evidence of retained mental capacity, lack of such ability may help to establish lack of capacity. Accordingly, the distracters should not be so obviously incorrect as to "guide" the testator to the correct answer, and the probability of a correct guess must be taken into account. To minimize the possible effects of "coaching" and sporadic situational factors that may detract from the testator's initial performance, this part of the evaluation should be administered twice, with the administrations separated by at least 5 minutes of unstructured interview.

The interviewer should also focus on contents of the testamentary document that are identified by counsel as likely to be challenged. This is done by asking the testator to discuss the reasons and motives behind each such decision. These responses will form the basis for the examiner's assessment of the testator's grasp of circumstances, use of logic and reason, and capacity for reality testing.

### *Undue Influence*

Thorough assessment of the possible exertion of undue influence requires examination of the testator as we have described, along with assessment of the testator's physical and social circumstances. This assessment should focus on the indicia of undue influence that we have listed, as well any other features that may be conducive to control and manipulation of the testator's emotions, beliefs, and behavior. The literature on contemporary religious cults may be helpful in this regard. For example, Streiker (13) listed elements commonly used by such cults that he describes as "a formula for evoking instant conversion" to the belief system of a group. Although some of these elements may occur in any intimate relationship, their coercive power appears to increase when they are applied simultaneously and persistently. They include secluding; providing attention, affection, and approval; encouraging behavioral regression and dependency; depriving mental and physical privacy; repeatedly presenting an organized body of data (indoctrination); reinforcing new behaviors consistent with desired beliefs; and discouraging independent thought by negative characterization.

The clinical examination should focus on any content areas related to the testamentary document that evoke hesitancy, uncertainty, or inconsistency on the part of the testator (e.g., "You seem uncertain about the decision to leave so much of your estate to Smith. How did you arrive at that decision?" or "You've indicated that you have not been a religious person, yet you are intending to leave a substantial amount of money to a religious organization. Can you explain this?"). Similarly, one should explore in detail the testator's thoughts and feelings about natural heirs who are to be disinherited or treated less favorably than may be expected or individuals who are unexpectedly named as beneficiaries.

*Case 1.* Mildred had always been Ms. A's favorite daughter, while Ms. A had always been critical of and did not get along with her other daughter, Edith. When Ms. A was 82 years old and had become legally blind, crippled, and completely dependent on others for existence, Edith volunteered to move into her mother's very expensive house to be her caretaker. Although Ms. A resented this arrangement and continued to be critical of Edith's habits, after about a year Edith arranged for Ms. A to change her long-extant will and bequeath the house to her rather than to Mildred. Mildred asked Ms. A's attorney to arrange for psychiatric evaluation of her mother. When the topic of which daughter was to get the house came up during the evaluation, Ms. A became anxious and uncomfortable, made several inconsistent statements, and appeared to exaggerate what had been, up to that point, only mild memory and language difficulties, as if to evade the question by being "unable" to understand it. In light of the physical and social circumstances, the psychiatric consultant gave the opinion that Ms. A was under Edith's undue influence.

## RETROSPECTIVE EVALUATION

### *Testamentary Capacity*

Because direct evidence is often not available, retrospective evaluation of testamentary capacity may be entirely inferential. However, despite the pessimistic note registered by Redmond (1) that we have cited, in many cases descriptive information provided by the surviving spouse, friends, relatives, business associates, and service providers regarding the testator's behavior can be very informative. Similarly, medical records, business records, and personal documents such as family films and videotapes, along with checkbook records, personal correspondence, notebooks and diaries, and even the will itself (if it is "holographic," i.e., handwritten), which directly reflect the testator's mental capacity, may provide data adequate to support a reasonably strong inference regarding testamentary capacity.

Medical records may contain formal diagnoses of mental or physical illnesses that could compromise mental function. If they do, it is important to scrutinize the records for descriptions of the testator's behavior and documentation of formal clinical examination of mental status, psychological tests, or other data that support the diagnoses and indicate lost and preserved mental capacities and the presence or absence of delusional beliefs. It is often fruitful to interview also the authors of the record, who may clarify or supplement the information presented.

*Case 2.* Ms. B was discharged from a psychiatric ward weeks before she amended her will and left all of her property to the manager of the board-and-care home where she was to spend the last months of her life. Her niece, the only surviving heir, challenged the will on the basis of lack of testamentary capacity and insane delusion. The medical record contained nursing notes indicating that Ms. B, in 6 weeks of hospitalization, was never able to find her own room on the ward, could not distinguish her own clothes from those of her roommates, never learned her nurse's name, and consistently thought she was in a different state. Physicians' notes indicated that Ms. B thought that her niece was "in cahoots with the Mafia and was trying to have her killed." She had also expressed the belief that her niece was actually dead and had been replaced by an impostor. On the basis of this record, supported by deposition testimony, the consulting expert gave the opinion that Ms. B lacked testamentary capacity and that the codicil was the product of an insane delusion.

Other records, including notes of the attorney who prepared the will or codicil, based on his or her meetings and conversations with the testator, may also provide valuable evidence relating to testamentary capacity. In most states this material is held to be accessible (i.e., no longer privileged) after the testator's death if the issue of capacity is raised. Records that contain entries made by the testator or that reflect the testator's unassisted knowledge and judgment may provide direct evidence of the testator's memory, language and higher intellectual functioning, judgment, and visuospatial skills.

*Case 3.* Ms. C's heirs challenged the validity of her will on the basis of lack of testamentary capacity, which they claimed was demonstrated by her sale of a valuable piece of income property a few months before her death. During this period she suffered some impairment in memory and self-care, which the expert was able to characterize as quite mild. However, because the sale price of the income property was significantly below market value, the contestants maintained that Ms. C, known for her shrewdness and business sense, could not have agreed to such a price unless she was intellectually impaired enough to lack testamentary capacity also. After examining several of Ms. C's personal notes and documents related to the sale, the consulting expert was able to determine, with the assistance of a tax expert, that the details of the transaction (including the price) were carefully calculated to effect a quick sale that would take advantage of an anticipated change in the tax law. Had Ms. C lived, the actual sale would have been more to her financial advantage than a sale for a higher price that might have taken a few more months to complete. The transaction, in light of the expert's other observations, provided strong evidence that Ms. C's judgment and reasoning ability were relatively intact, in spite of her failing memory and capacity for self-care.

Deposition testimony of the surviving spouse, friends, relatives, business associates, and involved professionals regarding the testator's behavior may supplement information obtained by direct interview, particularly if the psychiatric consultant has the opportunity to advise counsel regarding the most fruitful content areas to explore when taking the depositions. Again, the most valuable information from such sources is information related to the testator's behavior at or near the moment that the challenged testamentary document was signed.

Interpretation of data from these sources necessarily depends mainly on the expert's clinical experience with similarly affected individuals, as there is very little scientific or clinical literature that correlates cognitive capacities relevant to one area of functioning with those of another. However, a few studies correlating behavioral and cognitive capacities in patients at different stages of Alzheimer's disease (14) may be of value in some cases in which Alzheimer's disease is the probable diagnosis.

### *Undue Influence*

The relevant issue in retrospective determination of undue influence is, Did the testator suffer mental illness that rendered him or her particularly susceptible to undue influence at or before the time the challenged testamentary document was signed, and were personality features and social and environmental factors during the same time period more or less conducive to the exertion of undue influence? Again, in the absence of published research indicating which mental illnesses affect susceptibility to influence, the expert must rely on clinical experience. The experience of one of us (J.E.S.) suggests that any debilitating mental or physical illness resulting in dependence on caretakers will increase susceptibility to influence, while conditions associated with impaired critical judgment (such as mania or hypomania) or impaired reality testing (such as delusional disorder or schizophrenia) seem to reduce patients' ability to resist influence even in the absence of significant dependency. Dementias of all types, depending on the stage, seem to increase susceptibility to influence through effects on judgment and reality testing, whereas they reduce susceptibility to the extent that suspiciousness, paranoia, and exaggerated premorbid character traits (such as stubbornness, suspiciousness, and irascibility) are present. The effects of other psychiatric conditions and of other individual personality traits and constellations thereof on susceptibility to influence appear to be more variable. The psychiatric consultant should be prepared to formulate an opinion that takes into account the indicia of undue influence, the testator's personality traits, signs and symptoms of mental illness, and their effect on susceptibility to influence.

*Case 4.* Ms. D's grandchildren sued to overturn her will, in which she left her entire estate to her husband of only 5 years. The basis of the claim was that her husband, 50 years her junior, had exerted undue influence so as to cause her to be angry with and ultimately disinherit the grandchildren. Deposition testimony of Ms. D's friends and neighbors indicated that she had been independent to the point of belligerence and had consistently expressed her love and admiration for her husband, over whom she was seen as quite domineering. The consulting psychiatrist was also given access to more than 100 cards and letters exchanged by Ms. D and her daughter (deceased at the time of trial) and grandchildren over a 7-year period. These documents clearly revealed longstanding and increasing enmity between Ms. D and her daughter and grandchildren that preexisted the entry of Ms. D's husband into her life. This enmity did not increase after he entered the picture; rather, his influence, as reflected in the cards and letters, appeared to soften Ms. D's hostility toward her natural heirs. The consultant's opinion was that conditions favoring influence did not exist and that Ms. D left her money to her husband so that her natural heirs would not get it.

## ORGANIZING TESTIMONY

Expert testimony must initially establish to the court's satisfaction that true expertise exists in the area of the proffered testimony, that the witness has a legitimate claim to such expertise, and that such expertise is needed in order to arrive at the witness's conclusions. When allowed to testify, experts can present opinions as evidence, even if the opinions are based on information that would not otherwise be admissible (e.g., hearsay), as long as the information and the methods used to gather it are of the type reasonably relied upon by experts in the same field. As a general principle, expert testimony is strengthened if the expert presents the factual basis for his or her opinions, avoids technical jargon whenever possible, and acknowledges the limits of his or her expertise.

With these considerations in mind, we propose the following rules of thumb, which aim at enhancing the clarity and quality of expert testimony but are not intended to replace appropriate consultation between the expert and the attorney. An opinion about testamentary capacity, whether based on examination of the living testator or on retrospective review of evidence, should include comment on 1) the testator's global mental status, supported where possible by scores on standardized instruments; 2) the specific aspects of the testator's mental functioning believed to be most germane to the question of testamentary capacity (e.g., orientation, recent and remote memory, expressive and receptive language functioning, reality testing, judgment and reasoning); 3) the implications of these observations with respect to the specific elements of testamentary capacity (i.e., understanding the nature of the testamentary act, remembering and understanding relatives and assets); and 4) a diagnostic impression.

If the testator meets the criteria for a psychiatric diagnosis but retains testamentary capacity, the expert is advised to clarify the distinction between that diagnosis per se and the testator's level of functioning. This testimony is recommended to offset the commonly held false assumption that certain conditions (e.g., Alzheimer's disease) automatically render their victims incompetent for any decisions. Noting how this misassumption regarding Alzheimer's disease has permeated the fabric of law and judicial procedure, Rosoff and Gottlieb (15, p. 12) stated, "Laws and procedures currently followed in many states are inflexible and insensitive . . . and do not distinguish appropriately among the various levels of a person's competence." In this regard the expert may wish to cite examples—such as the college professor or corporate executive with Alzheimer's disease who is still able to function, albeit with reduced effectiveness in his or her professional role—in order to facilitate the judge's or jury's understanding that an individual with this illness may retain testamentary capacity despite the diagnosis.

Testimony regarding undue influence is structured similarly, covering 1) the testator's personality and global mental status; 2) specific personality traits, functional symptoms, cognitive deficits, and physical and social circumstances that could affect susceptibility to influence; 3) the implications of these in light of the elements of presumptive undue influence, the "indicia" of undue influence, and any perceived discrepancies between testamentary content and the testator's attitudes, goals, and values; and 4) a diagnostic impression.

To "wrap up" the direct examination, counsel may elicit the expert's opinion on the "ultimate issues" of the case, namely, whether the testator possessed testamentary capacity and whether he or she was free from undue influence. Although it was formerly within judicial authority to prohibit such testimony (on the theory that to give such opinions is, in effect, to render a legal judgment and thereby usurp the role of the trier of fact), the trend in recent years has been to follow rule 704(a) of the *Federal Rules of Evidence,* which states, in part, "Testimony in the form of an opinion or inference otherwise admissible is not objectionable because it embraces an ultimate issue to be decided by the trier of fact" (16), and the "helpfulness standard" (17), which essentially allows experts to provide any testimony within their range of expertise that will "aid the trier of fact in his search for the truth."

# Community Mental Health and Mental Retardation Services in the United States: A Comparative Study of Resource Allocation

**David Braddock, Ph.D.**

*Objective: Preliminary studies suggest that during the 1980s, spending for community mental retardation services in the United States may have grown much more rapidly than spending for community mental health. The primary objective of this study was to test empirically the validity of this thesis on a national basis. An additional objective was to determine why such a distinction in community spending patterns might have evolved nationally. Method: The study used states as the units of analysis and employed a five-factor hierarchical regression to predict variance in mental health and mental retardation spending. Factors were state size, state wealth, degree of federal assistance, state civil rights activity, and strength of consumer advocacy groups. Strong roles for the civil rights and consumer advocacy factors were hypothesized. A collateral opinion survey in the 10 states exhibiting the greatest within-state difference in community mental health and mental retardation spending was also completed. Results: Community mental retardation spending grew nearly four times more rapidly than community mental health spending in the 1980s. The consumer advocacy and civil rights factors were strongly associated with spending for community mental retardation services in the states, but these factors did not predict spending for community mental health services. Conclusions: Study recommendations included strengthening mental health family and consumer advocacy groups in the states and promoting systematic exchange between the mental health and mental retardation fields through joint state planning initiatives, studies, and conferences. The need for Medicaid reform is a unifying theme in both the mental health and mental retardation fields.*

(Am J Psychiatry 1992; 149:175–183)

For 221 years the U.S. state governments have been authorized by law to allocate funds for the care of persons with mental disabilities (1). For most of this period, the quantity of state government resources allocated for mental health services has dwarfed the level of funding available for mental retardation services. Thirty years ago, for example, the Illinois Department of Mental Health allocated $61 million for mental health services and $11 million for mental retardation programs (2). In the 1970s, the federal government became actively involved in financing services for persons with mental retardation through the adoption of the reimbursement program of the Medicaid Intermediate Care Facilities for the Mentally Retarded. Extensive class action litigation, coupled with vigorous advocacy

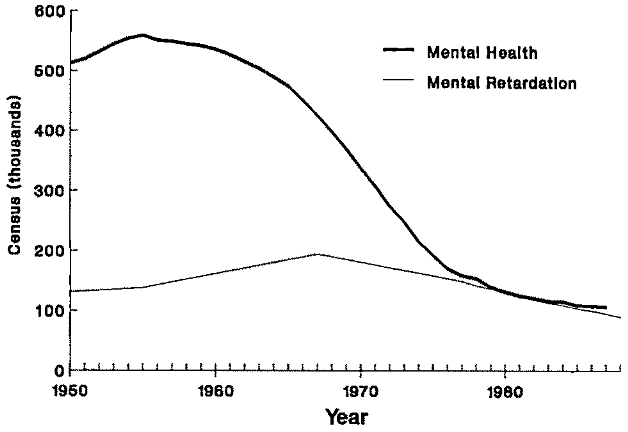
**FIGURE 1. Daily Census of State Mental Institutions: 1950–1988**[a]



[a]Mental health data from Witkin (5); mental retardation data from Lakin (6) for 1950–1976 and from Braddock et al. (3) for 1977–1988.

by associations for retarded citizens, helped stimulate a dramatic expansion of mental retardation resources in the states. By fiscal year 1983, a roughly equivalent sum of money—$6.93 billion versus $6.81 billion—was being budgeted across the country in state agency programs that served persons with mental retardation and closely related developmental disabilities (3) and in state mental health programs (4), respectively.

As shown in figure 1, roughly comparable numbers of individuals were being served nationally in 1988 in terms of the average daily census in state-operated mental retardation and mental health institutions. In contrast, community mental retardation services grew at an unprecedented rate in the states during the 1980s (3, 7–9). In 1977, the resident census in the nation's 4,290 community mental retardation residential facilities was 62,397 (10). In 1988, according to a national study by the University of Illinois at Chicago, more than 174,000 mentally retarded persons resided in community residential settings, excluding nursing homes (3). The total number of community mental retardation residential facilities exceeded 15,000 units in 1982 (11) and 28,000 units in 1988 (8). Recent assessments, however, have consistently stressed the limited development of supported community living for persons with mental illness in the states (12–19). In its widely disseminated "Proposal for Public Policy on the Chronic Mental Patient," APA described the lack of community mental health services as a "national crisis" (14, p. 209).

## APPROACH

The central purpose of this study was, using state governments as the basic unit of analysis, to compare recent trends in public spending for mental health and mental retardation services in the United States. Guiding the study was a strong suspicion that funding for community mental retardation services at the state level was, throughout the 1980s, growing much more rapidly and had achieved much greater total volume than had similar funding for community mental health services. Assuming that this was true, the important research question then was: why does this distinction in spending exist and what can be done to spur the development of community mental health services in the states using lessons learned from the recent expansion of community mental retardation services?

A substantial body of theory in mental health research literature ascribes a critical role to consumer advocacy groups, such as the Association for Retarded Citizens of the United States and the National Alliance for the Mentally Ill (NAMI), in stimulating the growth of community services (15, 17, 18, 20–22). Studies in juvenile delinquency (23), consumer protection (24), unemployment compensation (25), and, more recently, in mental retardation (26) have identified interest group activity as an important covariate of innovative state programs and spending policies in these fields. In mental retardation, associations for retarded citizens have operated professionally staffed government affairs units influencing public appropriations policies since the late 1950s. Associations for retarded citizens, in fact, were often the moving parties or plaintiff interveners in key litigation in the states. Thirty-eight right-to-habilitation class action lawsuits in mental retardation were filed in 27 states and the District of Columbia between 1971 and 1980 (27). Similar cases were litigated throughout the 1980s (e.g., *Homeward Bound, Inc. v. Hissom Memorial Center*) (28). This litigation frequently resulted in court orders or consent agreements virtually compelling defendant state agencies and governors to request substantially increased legislative appropriations for mental retardation services (29).

In a study of seven states, Wilson and Kouzi (20) attributed the "superior conditions of the homes for the developmentally disabled" and their higher mean funding level per client to the "relatively strong political position of national organizations that lobby for the interests of persons with these disabilities" (p. 317). Elpers (30) credited "relatives of the developmentally disabled" and their "powerful lobby" as an important basis for California's favored budgeting of funds for this group in recent years (p. 803). Winkle's New Jersey study (31) found that local organizations advocating for the interests of individuals with developmental disabilities were more likely than local mental health organizations to have family members instead of professionals or concerned citizens on their boards. Local organizations for individuals with developmental disabilities were also more likely to be associated with national and state organizations. Ross (32), a Washington lobbyist with experience in developmental disabilities and mental health organizations, has noted the relatively greater political strength of mental retardation and developmental disabilities advocacy groups nationally. He attributed this greater strength to the more extensive involvement of family members in developmental disabilities advocacy groups. Wilson and Kouzi (20) speculated that the social stigma accompanying mental illness (21, 33, 34) has inhibited community mental health advocacy more than stigma has inhibited the development of advocacy groups in the mental retardation field.

Bachrach (35) has observed that the civil rights advocacy movement has been a more potent instrument of community integration in the mental retardation field than in mental health. The social reform ideology of civil rights, according to Bachrach, is only one of several important factors giving rise to the deinstitutionalization of persons with mental illness. Other crucial factors include the introduction of antipsychotic medications and the development of crisis intervention techniques.

## METHOD

### *Analysis of Spending*

The present study was designed to test empirically Bachrach's assumption about the different roles of civil rights in the mental health and mental retardation fields and also to investigate the impact of consumer advocacy on public spending in both fields. The initial task was to compare the budgetary outputs of state political systems for mental health and mental retardation services. State government executive budget data for fiscal years 1981, 1983, 1985, and 1987 were employed for this purpose. Data sets for mental health and mental retardation spending in the states were obtained from the National Association of State Mental Health Program Directors (4) and the University of Illinois at Chicago (3). Minor modifications in the two data sets, described in a monograph available from me, were implemented to improve data comparability. Next, mental health and mental retardation fiscal effort indices were computed for each of the states for institutional and community services. This involved dividing each state's total spending for mental health and mental retardation services by that state's aggregate annual personal income. Statewide personal income data were obtained from the U.S. Bureau of Economic Analysis. Fiscal effort was computed for fiscal years 1981, 1983, 1985, and 1987 and also cumulatively across the entire 7-year period. Data were expressed in real economic terms (36).

### *Predictors of Community Spending*

Fiscal effort across fiscal years 1981–1987 served as the dependent variable in two hierarchical regressions—one for community mental retardation spending in the states and one for community mental health spending. The predictors included state size, state wealth, and degree of federal financial assistance for community programs. These factors have been commonly associated with state government spending in education, public welfare, corrections, natural resources, and transportation (3). However, the three predictors did not predict state-to-state variance in community mental retardation spending in a preliminary study (37). Gray's civil rights index (38) was significant in predicting community mental retardation fiscal effort in a subsequent study (26), and it was employed in both regressions in the present study. The civil rights index measured the rapidity of adoption of three state civil rights laws in public accommodations, fair housing, and fair employment practices.

The fifth variable in the regression equation, consumer advocacy, was operationalized in terms of per capita membership in state chapters of the Association for Retarded Citizens of the United States and in NAMI. NAMI is a family-based consumer organization concerned with serious mental illness. Like units of the Association for Retarded Citizens, NAMI membership consists primarily of relatives of persons with challenging mental disabilities. Torrey et al. (18) wrote that NAMI was "the single most important political force to emerge for the seriously mentally ill in this century" (p. 100). Chandler (15), Lefley (21), and Santiago (17) also specifically acknowledged NAMI's growing political significance in influencing state and federal policy in the mental disabilities field during the 1980s. A special telephone survey of membership in state and local NAMI chapters was conducted for the present study, whereas the Association for Retarded Citizens of the United States provided state-by-state membership figures. Consumer advocacy in the Association for Retarded Citizens and NAMI was computed on the basis of 1988 state membership as a percentage of each state's general population (39).

A second, paired set of regression analyses was also conducted on institutional fiscal effort in the states. The purpose of this second set of analyses was to contrast the five-factor regression across both the community and institutional sectors. The same five predictors employed in the two community mental health and mental retardation regressions—state size, wealth, federal assistance, civil rights, and consumer advocacy—were also employed in the institutional regressions.

### *Definitions*

*Institutional spending for mental retardation services* included operating funds from the Intermediate Care Facility for the Mentally Retarded program and state general revenue for state-operated institutions with 16 beds or more, developmental centers, training centers, state schools, and mental retardation units in state psychiatric hospitals (N=290). *Institutional spending for mental health services* included state general revenue and Medicaid and Medicare for treatment and services in 284 state psychiatric hospitals. *Community mental retardation spending* consisted of federal and state funding for publicly or privately operated community residential facilities and for nonresidential services such as habilitation, day training, sheltered work, supported and competitive employment, family support, early in-

[a]Mental health data adapted from the National Association of State Mental Health Program Directors (4, tables 40 and 41); mental retardation data adapted from Braddock et al. (3).

tervention, and case management (3). *Community mental health spending* included federal and state funds for programs administered by state mental health agencies that supported treatment, rehabilitation, and residential care in community settings.

## RESULTS

### *Analysis of Trends*

During the 1980s, community mental retardation services were funded with greater intensity in the states than were community mental health services. Between fiscal years 1981 and 1987, state government spending for community mental health services increased 27% in real economic terms. In the same period, real spending for community mental retardation services increased by 96%. Unadjusted spending for community mental retardation state government general fund commitments from own-source state revenues (i.e., excluding federal funds) increased by $2.2 billion during fiscal years 1981–1987; state general fund own-source support for community mental health services grew by $0.93 billion over the same period. Growth in state mental retardation spending was further enhanced by an acceleration in funding for community services through the federal Intermediate Care Facilities for the Mentally Retarded and Home and Community-Based Services Waiver programs. Federal Intermediate Care Facilities for the Mentally Retarded reimbursements, excluding state matching funds, advanced from $244 million to $842 million between fiscal years 1981 and 1987. Initiated in fiscal year 1982, federal Home and Community-Based Services Waiver funds for mental retardation grew from $1.2 million to $166 million in fiscal year 1987 (3). By fiscal year 1991, the mental retardation Home and Community-Based Services Waiver program served 48,000 clients in 43 states and involved nearly $900 million in state and federal expenditures (40). Home and Community-Based Services Waiver funding for mental health services was $792,000 in fiscal year 1987 (41, 42).

Trends in spending for both institutional and community services in the United States during fiscal years 1981–1987 are illustrated in figure 2. In fiscal year 1987, total spending for mental retardation services in the states was $9.98 billion versus $8.83 billion for mental health. Community mental retardation outlays in fiscal year 1987 were 72% higher than those for community mental health ($5.08 billion versus 2.96 billion). Wide variations among the states in spending for community services as a share of statewide personal income were observed. In fiscal year 1987, community mental health spending levels ranged from $1.98 to $0.06 per $1,000 of personal income in Massachusetts and Iowa, respectively; community mental retardation spending levels ranged from $3.31 to $0.41 in North Dakota and Nevada (table 1). Mean expenditures in the United States for community mental health and mental retardation services were $0.82 and $1.40 per $1,000 of personal income, respectively.

It was initially suspected that the ratio of mental retardation funds allocated for community and institutional services in the nation would be larger than the ratio of funding for mental health services. This was confirmed. The proportional relationship nationally between cumulative (fiscal years 1981–1987) mental retardation and mental health funding for community and institutional services was 44% versus 56% (mental retardation) and 32% versus 68% (mental health). These percentages for community and institutional spending, respectively, reflect the adjusted *cumulative* trend for the 7-year period. They do not, however, reflect the *direction* of the trend. Between fiscal year 1981 and fiscal year 1987, community mental retardation spending as a percentage of total mental retardation spending increased from 35% to 51%. In contrast, during the same period, spending for community mental health services as a percentage of total mental health spending grew from 30% to 34%. Moreover, much of the percentage growth in mental health spending was

[a] Mental health data adapted from the National Association of State Mental Health Program Directors(4); mental retardation data adapted from Braddock et al. (3).

attributed to the deployment of Alcohol, Drug Abuse, and Mental Health Administration Block Grant funds directly to state mental health agencies after fiscal year 1982. Before August 1981 these funds were allocated directly by the federal government to community mental health agencies. In fiscal terms, state mental retardation agencies were involved in a more dynamic transformation from institutional to community services than were their counterparts in mental health.

### *Results of Regression Analyses*

Results of the community mental health regression were not statistically significant. State size, state wealth, federal aid, civil rights activity, and consumer advocacy failed to account for any appreciable variance in the equation (F=1.16, df=5, 39, p>0.05. A modest simple correlation (r=0.30, p<0.05) was observed between community mental health spending and the civil rights factor. The regression of state size, state wealth, federal aid, civil rights innovativeness, and Association for Retarded Citizens consumer advocacy was statistically significant for community mental retardation spending ($F=8.42$, $df=5, 42$, $p<0.001$). Fifty percent of the variance in the regression equation was accounted for. However, the advocacy and civil rights factors accounted for over 90% of this explained variance. State size, state wealth, and federal aid for community programs were not significant predictors in the mental retardation regression ($F=0.74$, $df=2, 42$, $p<0.05$).

Hierarchical regression analyses were also carried out for institutional fiscal effort in mental health and mental retardation. Neither yielded a statistically significant overall equation ($F=1.84$, $df=5, 42$, $p>0.05$ and $F=2.09$, $df=5, 42$, $p>0.05$, respectively). The Association for Retarded Citizens consumer advocacy factor did account for a statistically significant increment in predicted variance in the institutional regression equation ($F=9.59$, $df=1, 42$, $p<0.01$). Thus, a higher per capita rate of state Association for Retarded Citizens membership was associated with a greater level of fiscal effort for both community and institutional mental retardation services in the states.

### *Collateral Survey of 10 States*

Collateral evidence of the degree to which various factors might account for state-by-state variance in fiscal effort for community mental health and mental retardation services was explored in a telephone survey involving 40 individuals from those 10 states exhibiting the greatest within-state percentage variance in community mental health and mental retardation spending in fiscal year 1987. All 10 states expended more funds for community mental retardation services than for community mental health. The interviewees included four representatives from each of the 10 states: two executives from the community services component of the state mental health/mental retardation agencies, including one program leader from the mental retardation division and one from the mental illness division; and two from the consumer advocacy sector, including one from the state Association for Retarded Citizens chapter and one from the state NAMI office. The 10 states were Colorado, Connecticut, Iowa, Maine, Maryland, Michigan, Montana, Nebraska, New York, and Pennsylvania.

The survey probed reasons underlying these states' relatively greater funding levels for community mental retardation services. The interviewer randomly listed several potential reasons including favorable federal government policies; strength of consumer advocacy groups; effect of class action litigation; and leadership of key legislators, state agency directors, governors, and the media. In addition, interviewees were asked to identify other factors creating the wide disparity in the proportion of funding allocated in their state for community services. All 40 interviewees' comments were transcribed by the interviewer and categorized. A second analyst independently attempted to replicate the classification of the first in a reliability assessment using the kappa statistic (kappa=0.97) (43).

Thirty-five of the 40 respondents (88%) stated that Association for Retarded Citizens advocacy was an important factor in the greater level of financial commitment in their state for community mental retardation services. Extent of agreement between the mental health and mental retardation respondents on the importance of the Association for Retarded Citizens advocacy factor was high (kappa=0.72). All four respondents from each of eight states and three of four from a ninth state cited the crucial importance of the Association for Retarded Citizens consumer advocacy factor. The impact of class action litigation in mental retardation and the increased stigma of mental illness were also cited frequently by the respondents (18 and 15 times, respectively).

## CONCLUSIONS AND IMPLICATIONS

### *Divergent Patterns of Community Spending*

Widely divergent community mental health and mental retardation spending patterns in the states were identified in this study. Analysis of the predictors of spending underscored these differences. Political culture in the states, as represented by the civil rights index in the regression analyses, was a major covariate of mental retardation spending, yet it was only weakly correlated with mental health fiscal effort. This finding is consistent with Bachrach's observation (35) about the more potent influence of civil rights in the mental retardation field. Remarkably, the 10 most highly ranked states in community mental retardation fiscal effort for fiscal year 1987 (table 1) were each the site of major class action right-to-habilitation litigation. In four of these 10 states (North Dakota, New York, Connecticut, and Michigan) the state Association for Retarded Citizens chapter was the moving party in the case. Associations for retarded citizens were plaintiff interveners in Rhode Island, New Hampshire, and Pennsylvania; *amicus curiae* in Minnesota; and the court monitor in the Washington, D.C., case.

Consumer advocacy was an important predictor of community mental retardation spending; however, it was not significant in the mental health regression. Why the predictive power of the consumer advocacy factor should be so different across the mental health and mental retardation sectors is a provocative question. There are several plausible hypotheses. NAMI formed nationally in June 1980 (44). During the period of this analysis, most NAMI chapters lacked the membership base, operating experience, and professional government affairs components enjoyed by state and national Association for Retarded Citizens units. The failure of the consumer advocacy factor to predict any variance in the community mental health regression might well be attributed to the brief tenure of NAMI as a functioning organization and to the emphasis in this analysis on identifying nationwide variance in the regression. Had the study focused in greater depth on NAMI's activities in specific states, discovering relationships between NAMI's activities and enhanced community spending in those states would have been more likely (17). In Maryland, for example, NAMI's activities as part of a citizens' advocacy coalition were instrumental in securing an increase in the state's community mental health budget from $20.4 million in fiscal year 1983 to $55.2 million in fiscal year 1988 (45).

Mental health organizations such as NAMI and the National Mental Health Association may lack the singularity of focus of the associations for retarded citizens on a community integration agenda (45, 46). The Association for Retarded Citizens for the United States has adopted unequivocal national policy statements calling for phasing out institutions in lieu of integrated community living arrangements (47). Legislative success in the American states varies inversely with internal interest group conflict. Groups displaying greater agreement among themselves as to fundamental objectives enjoy greater success in creating legislative outcomes favorable to their interests (48). While acknowledging the "useful beginnings" of NAMI chapters, Mechanic (22) has noted that advocates for mentally ill persons are "divided by categories of disorder, by treatment modalities, and by preferences for particular sites of care" (p. 895). Instead of forming common objectives, mental health advocates weaken their impact by competing with one another over "contested terrain" (15). Cromwell et al. (45), representatives of Maryland's chapters of the National Mental Health Association and NAMI and a provider organization, identified the greatest challenge facing the community mental health movement as "building consensus on positions and advocacy strategies, and [acting] with unity" (p. 960).

A third plausible hypothesis regarding differences between the impact of mental retardation and mental health advocacy has to do with the *political implications of stigma*. Chronic mental illness is among the most stigmatizing of disabling conditions—many authorities argue that it is even more stigmatizing than mental retardation (33, 34, 49). Stigma has discouraged relatives of mentally ill persons—and mentally ill persons themselves—from organizing consumer advocacy organizations in the states. Lack of consumer advocacy has prevented the expansion of resources for community mental health services. Approximately 40% of the interviewees in the 10-state survey cited the impact of stigma in mental illness as an inhibiting factor in the expansion of community mental health resources.

A fourth possible factor contributing to the difference in state spending has to do with a basic dissimilarity in the financing of the two community service delivery systems. Third-party reimbursement from private insurance plays a proportionately larger role in financing community mental health services than it does in supporting community mental retardation programs. According to Tischler (50), 28 states have passed statutes since 1978 requiring private health insurers to provide coverage for mental health services. These mandates often shifted payment responsibilities from state mental health agency funds to private third-party sources (51). Because most third-party funds, and also most local funds, were not managed by the state mental health agencies, they were not included in the National Association of State Mental Health Program Directors data set used in this study for comparative analysis.

### *Sources of Community Growth*

The greater quantity of total spending for community mental retardation services in the states was due to the rapid growth of revenue from three sources. Listed in descending order of magnitude, they included state government own-source general revenues, Medicaid Intermediate Care Facilities for the Mentally Retarded funds, and federal Home and Community-Based Services Waiver Medicaid funds. State government own-source general revenue for community mental retardation services grew more than sixfold, from $0.48 billion in fiscal year 1977 to $3.22 billion in fiscal year 1987. This phenomenal 10-year growth pattern reflects the significance of the state legislative appropriations process for community services development and the singular importance of state-level consumer advocacy by groups such as the Association for Retarded Citizens.

Federal policy prohibits mentally ill persons from participating in the program of the Intermediate Care Facilities for the Mentally Retarded. Mentally ill persons between the ages of 22 and 64 are also ineligible to receive Medicaid-funded care in psychiatric hospitals. Hence, the Home and Community-Based Services Waiver Medicaid Program was not available to state mental health agencies for providing Medicaid-funded community services to the majority of adult persons with mental illness in the United States. This is in marked contrast with the mental retardation experience. A representative of the National Association of State Mental Retardation Program Directors recently commented that: "it is difficult to conceive how the states would have been able to expand community-based [mental retardation] services at the rate they have over the past few years in the absence of the waiver program" (40).

As currently structured, Medicaid is unable to cover the costs of care for adult, nonaged mentally ill individuals residing in small residential facilities such as group homes, adult foster homes, and halfway houses, even though extensive coverage for these services may be provided to persons with mental retardation at the option of the states. States do have the option to use Medicaid to cover a variety of important community mental health services ranging from targeted case management to psychosocial rehabilitation. Koyanagi (52), however, recently remarked that "it is impossible to find a single state with a Medicaid services package that provides comprehensive coverage . . . for adults or children" (p. 138). Professionals and advocates must continue to encourage the broadening of state and federal Medicaid coverage for community mental health services (53). Medicaid reform is also an urgent concern in the mental retardation field, but for different reasons: 84% of the more than $6 billion in state and federal funds deployed in 1988 for Medicaid Intermediate Care Facilities for the Mentally Retarded in the United States financed residential services in large congregate care facilities with 16 or more residents (26). The need for Medicaid reform is thus a unifying theme in both the mental health and mental retardation fields today.

### *Need for Systematic Exchange*

Bachrach (35) noted a decade ago that "surprisingly little systematic exchange has taken place between program planners [in mental health and mental retardation] . . . even though there have been remarkable parallels in the aims and purposes of deinstitutionalization for both of these mentally disabled populations" (p. 51). Mental retardation and chronic mental illness are discrete entities diagnostically, but the needs that individuals in both groups have for family-scale supported community living (35) and skills training (54) are unifying features of the two conditions. An important implication of this study is in encouraging comparative state-by-state studies of the expansion of community services for *all* persons with a serious mental disability regardless of the diagnosis. State planning initiatives, studies, and conferences should be jointly sponsored by public and private mental health and mental retardation constituencies such as associations for retarded citizens and NAMI chapters, state developmental disabilities planning councils, the National Institute of Mental Health, and other prominent organizations.

Led by active parent groups, the mental retardation field has established literally thousands of community living arrangements across the country during the past decade. Much remains to be accomplished, however. Many "community-based" placements have been in segregated, large congregate care facilities with too much in common with the state institutions that they are supposed to replace. Staff in community facilities are underpaid and turnover is extremely high (55). Waiting lists in the states for residential services have burgeoned beyond 60,000 persons (56), and more than 50,000 mentally retarded individuals are inappropriately residing in nursing homes (57). Still, a great deal of progress has been made in reconfiguring mental retardation service delivery systems in the states and in developing useful models of supported community living (58). During the 1981–1987 study period, an unprecedented 22 state-operated mental retardation institutions in nine states ceased operations. An additional 15 institutions closed or were scheduled to do so during the 1988–1992 period (59). Several states will be "institution free" by the mid-1990s, which is to say that their mental retardation service systems will be based entirely in community settings (59).

The situation in the mental health field remains, to use APA's terminology (7), a "national crisis" (p. 209). The number of mentally ill persons residing in nursing homes is nearly six times the number of persons with mental retardation residing in these facilities (60). Homeless individuals, about one-third of whom are mentally ill (12), number from 250,000 to 3 million depending on the study cited (61). State hospitals are very expensive to operate, and few states are generous in the allocation of community resources for persons with serious mental illness (16–18).

The mental retardation example of the 1980s has demonstrated that it is possible for the states to implement a substantial expansion of community services to individuals with mental disabilities, and it is possible to do so relatively rapidly. This study has demonstrated empirically that consumer advocacy and civil rights initiatives were important covariates of this dramatic expansion in community mental retardation resources in the states. Santiago (17) was correct in asserting that although the determinants of social reform are multivariate, there must first be "the creation and development of a social movement—a collective incentive of a grass roots nature—defining and guiding the reform" (p. 148). I believe that the decade of the 1990s will be characterized by a continuing aggressive pattern of growth in the allocation of resources for community mental retardation services nationally. A dramatic expansion of resources in community mental health is less certain. Unquestionably, this is long overdue and we must continue to press for its achievement.

# Cognitive Deficits of Patients With Alzheimer's Disease With and Without Delusions

Dilip V. Jeste, M.D., Robin E. Wragg, M.D., David P. Salmon, Ph.D.,
M. Jackuelyn Harris, M.D., and Leon J. Thal, M.D.

*Objective: The goal of this investigation was to study the prevalence of delusions in Alzheimer's disease and to compare the performance of the delusional and nondelusional groups on a neuropsychological test battery. Method: The authors studied 107 patients with Alzheimer's disease and 51 age- and education-comparable normal subjects using a standardized psychiatric interview and a neuropsychological test battery. Results: Thirty-seven patients with Alzheimer's disease had delusions with or without hallucinations. Patients with delusions were significantly more impaired than those without delusions (and the normal comparison group) on the Mini-Mental State examination; Blessed Information-Memory-Concentration Test; Dementia Rating Scale, especially its conceptualization and memory subtests; and a test of verbal fluency. The delusional group also tended to be somewhat more impaired than the nondelusional group on the modified Wisconsin Card Sorting Test and the similarities subtest of the Wechsler Adult Intelligence Scale-revised. Conclusions: Approximately one-third of patients with Alzheimer's disease had developed psychotic symptoms sometime after the onset of dementia. The presence of psychotic symptoms in Alzheimer's disease was associated with greater cognitive impairment, especially frontal/temporal dysfunction, and possibly with a more rapidly progressive dementia.*

(Am J Psychiatry 1992; 149:184–189)

Psychotic symptoms in some form affect a number of patients with Alzheimer's disease at some time during the course (1) of the illness. Reported figures for the prevalence of psychotic symptoms range from a low of 10% (2) to as high as 73% (3). A recent prospective investigation showed that psychotic and other potentially treatable psychiatric symptoms were important risk factors for institutionalization of patients with Alzheimer's disease (4). Modern psychiatric classifications have recognized a variant of Alzheimer's disease with delusions as a distinct subtype (*DSM-III* and *DSM-III-R*). Yet, despite the importance of psychotic symptoms in Alzheimer's disease, there have been relatively few large-scale prospective studies comparing patients with Alzheimer's disease with and without delusions and normal control subjects on demographic and neuropsychological variables. Furthermore, the studies that have been reported have often presented conflicting results. For example, divergent results and conclusions were obtained in six studies (5–11) that compared the degree of cognitive impairment in patients with Alzheimer's disease with psychotic symptoms to that in patients with Alzheimer's disease without psychosis. These studies reported no association (6), a trend toward a negative association (5), a positive correlation (7), or a mixed relationship (8–11) between psychotic symptoms and severity of dementia in Alzheimer's disease. The reasons for the discrepant findings in these studies are unclear. It should be mentioned that all of these investigations relied solely on screening tests for global cognitive impairment, such as the Mini-Mental State examination (12), rather than on more detailed neuropsychological testing.

Evaluating a possible relationship between cognitive deficits and the presence of psychotic symptoms may be important for understanding the pathophysiological basis of delusions and hallucinations in dementia and for early recognition and treatment of these symptoms in patients at different stages of dementia.

Various neurobiological as well as psychodynamic theories have been offered to explain the occurrence of psychotic symptoms in dementia (13, 14). Evidence in favor of each of those hypotheses is rather "soft." There is more evidence supporting limbic, especially hip-

pocampal-temporal and prefrontal, pathology in "functional" psychoses such as schizophrenia (15–17).

We undertook the present investigation to study the prevalence of delusions in Alzheimer's disease and to compare the performance of delusional and nondelusional groups on a battery of neuropsychological tests. If delusions in Alzheimer's disease are related to hippocampal-temporal or prefrontal pathology, then patients with Alzheimer's disease with delusions may have significantly greater impairment than patients without delusions on tests that are dependent upon the integrity of those brain regions.

## METHOD

### *Subjects*

A total of 107 patients with probable or possible Alzheimer's disease and 51 age- and education-comparable normal subjects participated in this study. (For the purposes of the present study, we excluded normal comparison subjects who had significantly higher levels of education than the patients with Alzheimer's disease). The patients with Alzheimer's disease and the normal comparison group were matched by group means for age (73 and 71 years, respectively) and education (13 years for both). Written informed consent was obtained from all subjects (or their conservators) after the procedures of the study had been fully explained.

The diagnosis of Alzheimer's disease was made independently by two senior staff neurologists at the university's Alzheimer's disease research center according to the criteria developed by the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (18). To reduce the possibility of including subjects with multi-infarct dementias, patients with a score of 4 or greater on the modified Hachinski Ischemia Scale (19) were excluded from the study. Participants with Alzheimer's disease were outpatients residing in the community and were capable of participating in detailed clinical, neuropsychological, and other laboratory evaluations. The patients had not been referred for the evaluation or management of neuropsychiatric or behavioral symptoms. Clinical care remained the responsibility of the primary medical provider. The comparison group of normal subjects consisted of either spouses of patients or volunteers obtained through newspaper advertisements. Subjects with a history of substance abuse, learning disability, or a serious neurological or psychiatric illness were excluded.

### *Procedure*

Each patient and normal comparison subject underwent a comprehensive evaluation at the university's Alzheimer's disease research center. As part of this evaluation, patients received a brief medical examination, a review of medical history including medications and demographic variables, a neurological examination, a psychiatric evaluation, and detailed neuropsychological testing.

*Psychiatric evaluation.* A semistructured interview based on the National Institute of Mental Health Diagnostic Interview Schedule (DIS) for *DSM-III* (20) was performed with each subject and/or the patient's caregiver informant. The DIS permits data collection from all relevant sources, including family members and caregivers, as well as ancillary medical records.

The DIS was administered to subjects and caregivers by experienced nurse practitioners trained in its use. Particular care was taken to distinguish between delusions (fixed and persistent false beliefs) and confabulations (fabrications in response to questions that cannot be answered because of memory loss) (*DSM-III-R*). Psychiatric diagnoses, both before and after the onset of Alzheimer's disease, were assigned by a board-certified psychiatrist (D.V.J.) on the basis of the DIS and other relevant data. The psychiatrist was blind to the subject's neurological diagnosis (i.e., Alzheimer's disease or normal) and neuropsychological test performance.

*Neuropsychological testing.* All of the patients and comparison subjects were evaluated with a battery of neuropsychological tests. The battery consisted of tests of overall mental status: Mini-Mental State examination (12) and Blessed Information-Memory-Concentration Test (21); attention: digit span subtest of the WAIS-R and attention subtest of the Dementia Rating Scale (22); memory: memory subtest of the Dementia Rating Scale; language: an abbreviated form of the Boston Naming Test (i.e., either the odd or even items) (23), Verbal Fluency Test, and the Number Information Test (unpublished 1984 paper of H. Goodglass et al.); problem solving, abstract thinking, and initiation: conceptualization and initiation subtests of the Dementia Rating Scale and the Verbal Fluency Test (24); and constructional ability: block design subtest of WISC-R, Clock Drawing Test, and the Dementia Rating Scale construction subtest.

All of the subjects with a Dementia Rating Scale score above 95 were given a more comprehensive battery that included the following additional neuropsychological tests: Modified Wisconsin Card Sorting Test (25); the similarities, vocabulary, and arithmetic subtests of the WAIS-R; the Visual Reproduction Test (26) of the Wechsler Memory Scale (27); the Buschke Selective Reminding Test (28); and the Trail-Making Test (parts A and B) (29). Of these tests, the Wisconsin Card Sorting Test and the similarities subtest may be most sensitive to frontal lobe dysfunction, while temporal-hippocampal dysfunction may be best assessed by the memory measures of the Buschke Selective Reminding Test and the Visual Reproduction Test.

## RESULTS

Psychiatric evaluation revealed that 37 of the 107 patients with Alzheimer's disease had developed delusions,

| Visual | 13 |
| Auditory | 7 |
| Olfactory | 2 |
| Tactile | 1 |

[a] A number of patients had more than one psychotic symptom.

with or without hallucinations, after the onset of dementia. Thirty of these 37 patients were delusional at the time of their assessment at the Alzheimer's disease research center. The remaining seven patients reported delusions in the past but were free of delusions at the time of their assessment. (These seven patients did not differ significantly from the other 30 on any relevant variable.)

At the time of assessment, nine of the 37 delusional patients were taking a neuroleptic, as were five of the 70 nondelusional patients (usually for treating agitation). Most of these patients were taking low doses of haloperidol (mean dose=1.8 mg per day). With one exception, no patient was taking anticholinergics. None of the patients had any noticeable extrapyramidal reactions, sedation, or confusion at evaluation.

Table 1 describes the types of delusions and hallucinations observed in the patients with Alzheimer's disease and the number of patients manifesting each type. The content of both delusions and hallucinations was usually simple and nonbizarre. The most common delusion, people stealing or hiding things, occurred in 65% of the patients with psychotic symptoms. (These patients had a fixed, firm, and false belief that one or more specific persons had intentionally stolen or hidden their belongings. Demented patients who forgot where they had kept certain things and merely considered a possibility that others might be hiding them were not considered delusional.) Hallucinations were most often visual in nature. They typically consisted of seeing one or more persons (familiar or unfamiliar to the patient).

There were no significant differences between the delusional and nondelusional groups of patients with Alzheimer's disease in mean age, level of education, and duration of illness (table 2). There was a nonsignificantly greater proportion of women in the delusional group (female-to-male ratio=21:16) than in the nondelusional group (female-to-male ratio=35:35). (The ratio of women to men in the normal comparison group was 33 to 18.) None of the patients had a past history of schizophrenia or delusional disorder. There was also no significant association between the presence of psychotic symptoms and the presence of myoclonus or other abnormal movements.

Table 2 presents the mean and median scores achieved by the patients without delusions, patients with delusions, and age- and education-comparable normal subjects on each of the neuropsychological tests given to the entire group of subjects. Group comparisons were performed with the Kruskal-Wallis one-way analysis of variance. All pairwise comparisons were performed with the Mann-Whitney U test. (Nonparametric statistics were preferred because the distribution of values on a number of tests was not normal.) As expected, both Alzheimer's disease patient groups were significantly impaired, relative to the normal comparison group, on all neuropsychological measures (all p values were less than 0.01). The neuropsychological performance was unrelated to current neuroleptic use.

Despite equivalent age, education, and duration of dementia, Alzheimer's patients with delusions performed significantly worse than Alzheimer's patients without delusions on the Mini-Mental State examination (12) ($p< 0.001$), the Blessed Information-Memory-Concentration Test (21) ($p< 0.002$), and the Dementia Rating Scale (22) ($p< 0.04$). The patients with delusions were more impaired than the patients without delusions on two of the Dementia Rating Scale subtests: the conceptualization ($p< 0.04$) and memory ($p< 0.03$) subtests.

The two patient groups performed similarly on the Boston Naming Test (23) and the Number Information Test (unpublished 1984 paper of H. Goodglass et al.). On the test of verbal fluency, patients with delusions generated significantly fewer exemplars from a particular category than did patients without delusions ($p< 0.04$). In contrast, the two groups performed similarly when generating words that begin with a particular letter. There were also no significant differences between the two groups on the WISC-R block design subtest or the Clock Drawing Test.

Figure 1 presents a frequency histogram of percentages of patients with Alzheimer's disease with delusions and those without delusions as a function of the Mini-Mental State examination (12) scores. Whereas almost one-half (47%) of the patients without delusions had Mini-Mental State examination scores higher than 20, less than a quarter (22%) of the delusional patients were in that category. More patients with Alzheimer's disease with delusions had Mini-Mental State examination scores between 11 and 20 (47%) than either above 20 (22%) or below 11 (31%).

The results of additional neuropsychological tests were available for 16 patients with Alzheimer's disease with delusions and 44 patients with Alzheimer's disease without delusions. These revealed no further significant differences between the groups (besides those on tests mentioned earlier for the entire sample of patients). There was, however, a tendency for the delusional patients to be more impaired than the nondelusional group on several tests including the modified Wisconsin Card Sorting Test (25) (means for perseverative errors=10.7, SD=11.5, for the nondelusional group and 13.0, SD=11.2, for the delusional group) and the similarities subtest of the WAIS-R (means=12.7, SD=5.9,

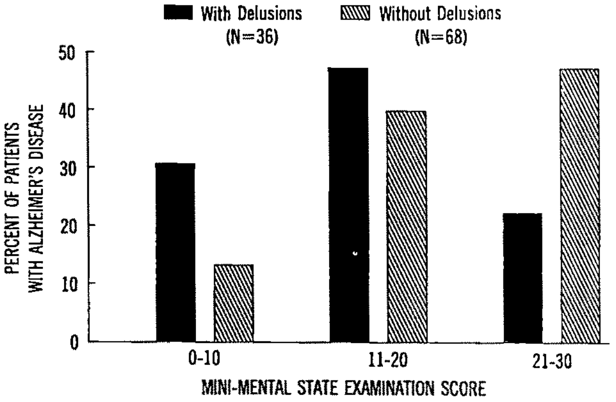
for the nondelusional group and 9.8, SD=6.5, for the delusional group).

## DISCUSSION

Cognitive dysfunction is the hallmark of Alzheimer's disease. Yet, noncognitive behavioral disturbances such as psychotic symptoms are also important from the viewpoint of management of patients with Alzheimer's disease. Surprisingly, the relationship between global cognitive impairment and psychosis in Alzheimer's disease is still not well understood. Even less is known about specific patterns of cognitive impairment associated with psychotic symptoms in Alzheimer's disease. Such information could potentially be helpful in learning about the possible underlying neurobiological basis of psychosis in patients with dementia.

Our finding of a 35% prevalence of delusions and 17% prevalence of hallucinations in patients with Alzheimer's disease is well within the range reported in the literature (1–3). In our study, the presence of psychotic symptoms was associated with a greater severity of dementia, although the delusions and hallucinations were found to be rare in patients with severe dementia.

**FIGURE 1. Distribution of Mini-Mental State Scores Among Patients With Alzheimer's Disease With and Without Delusions**



We should point out that our delusional and nondelusional groups of patients with Alzheimer's disease were similar in terms of duration of dementia, age, and education, and yet the psychotic group had significantly lower Mini-Mental State examination (12) and Dementia Rating Scale (22) scores and higher Blessed Information-Memory-Concentration Test (21) scores, indicating a greater degree of dementia. This suggests a possible association between the occurrence of psychotic symptoms and a more rapidly deteriorating course of dementia. Such a hypothesis would be consistent with the finding of Drevets and Rubin (30), who observed a faster cognitive deterioration in 10 patients with Alzheimer's disease with psychosis than in 15 nonpsychotic patients with Alzheimer's disease. Mayeux et al. (31) and Stern et al. (32) have reported that patients with Alzheimer's disease with both psychosis and a movement disorder have a rapidly progressive dementia. We did not, however, see evidence of a greater frequency of myoclonus or other movement disorders in our psychotic patients.

On neuropsychological testing, the delusional group performed significantly worse than the nondelusional group on a test of memory (the memory subtest of the Dementia Rating Scale [22]) and on two putative tests of frontal function (conceptualization subtest of the Dementia Rating Scale [22] and category subtest of the Verbal Fluency Test). Although the two groups did not differ significantly on the letter fluency task, patients with Alzheimer's disease with delusions performed significantly worse than patients with Alzheimer's disease without delusions on the category fluency. Since category fluency is more dependent than letter fluency upon the integrity of semantic memory (24), this pattern may be indicative of greater disruption in the organization of semantic memory (and greater frontal/temporal dysfunction) in patients with Alzheimer's disease with delusions than in those without delusions. Among patients with higher Dementia Rating Scale scores, the delusional patients with Alzheimer's disease tended to perform worse than nondelusional patients on two putative tests of abstraction, the similarities subtest of the WAIS-R and the modified Wisconsin Card Sorting Test (25); however, these differences did not attain statistical significance. While it would be speculative to draw conclusions about the specific brain localization of these neuropsychological deficits, they are at least consistent with possible frontal/temporal dysfunction. This may have an interesting relationship to the findings of limbic system pathology in schizophrenia—a psychosis characterized by delusions and hallucinations (15–17). Furthermore, Zubenko et al. (33) have recently reported an association between psychosis in Alzheimer's disease and increased densities of senile plaques and neurofibrillary tangles in specific cortical areas, especially the middle frontal cortex and the prosubiculum.

It is possible that psychotic symptoms may have interfered with a patient's performance during neuropsychological testing, creating an erroneous impression of greater cognitive deficits. This explanation is unlikely, however, since none of the patients had such florid psychotic symptoms that they obviously interfered with any of the testing procedures. All of the patients completed the extensive assessment at the Alzheimer's disease research center with excellent cooperation. In addition, the delusional patients did not differ from the nondelusional ones on the attention and initiation subtests of the Dementia Rating Scale (table 2).

The lower prevalence of delusions in severely demented patients could conceivably be an artifact of the patients' deteriorating verbal abilities. Alternatively, the decreased prevalence could mean that a certain amount of neuronal integrity is necessary for the occurrence of delusions. When a patient's language has deteriorated markedly, delusional thoughts cannot be verbally expressed.

A prospective long-term study would be useful in determining whether the development of psychotic symptoms indicates a more rapidly progressive dementia. In addition, functional brain imaging techniques such as positron emission tomography may be helpful in testing for frontal/temporal hypofunction in patients with Alzheimer's disease with delusions.

*Objective: Although the Global Deterioration Scale has been widely used since its publication in 1982, its stages are based on implicit assumptions about the linearity, temporality, and interdependence of cognitive, functional, and behavioral impairment in Alzheimer's disease. The authors evaluated the validity of these assumptions and tested the hypothesis that psychopathology and functional impairment would occur in earlier stages than the Global Deterioration Scale predicts. Method: The analyses were based on data on 324 patients with Alzheimer's disease who were selected from a registry of such patients. Data analyses included 1) descriptive statistics on the frequency of psychiatric symptoms and difficulties with activities of daily living and 2) logistic regression, with symptoms and functional impairment as independent variables, to test for significant changes in patients' status between stages of the Global Deterioration Scale. Results: More than 50% of the patients at stage 2 displayed psychopathology, and 32% had two or more symptoms. The significant increase in psychiatric symptoms occurred between stages 3 and 4, not between stages 5 and 6 as predicted by the Global Deterioration Scale. Impairment in functional status was observed at all stages, and significant increases occurred between stages 3 and 4 as well as between stages 5 and 6. Conclusions: Psychiatric symptoms and functional impairment occur earlier than predicted by the Global Deterioration Scale, and the rate of change is also different from that specified in the scale. Separate scales to describe cognitive, clinical, and functional status may be the best way to describe the illness until better multidimensional instruments are developed.*

(Am J Psychiatry 1992; 149:190–194)

---

Alzheimer's disease has been described as an unrelenting "loss of self" (1) characterized by progressive decline of cognitive and functional capacities as well as psychiatric morbidity (*DSM-III-R*, 2). The disease manifests itself in multiple ways, and there is considerable value in developing a scale to describe patients' status. However, limited data are available to document the incidence and prevalence of changes during the course of illness (3, and unpublished work of D. Cohen et al.), and significant variability has been reported in the rate of change in cognitive and noncognitive dysfunction (4–6). Such information is fundamental for the construction of accurate scales for global staging of Alzheimer's disease.

While a number of scales exist, one of the most widely used instruments to stage the course of Alzheimer's disease is the Global Deterioration Scale (7) for primary degenerative dementia. The Global Deterioration Scale is a seven-stage rating scale in which stage 1 reflects no cognitive decline, stage 2 reflects very mild cognitive decline, and stages 3–7 are defined, respectively, as mild, moderate, moderately severe, severe, and very severe cognitive decline. Each stage is associated with clinical phases ranging from normal (stage 1) to late dementia (stage 7), and each is also accompanied by a brief description of clinical characteristics (i.e., functional status, behavioral functioning, psychiatric problems) presumably associated with each stage. Finally, each stage has a diagnostic label: "normal" and "normal aged" for stages 1 and 2, "com-

patible with incipient Alzheimer's disease" for stage 3, and "mild Alzheimer's disease" to "severe Alzheimer's disease" for stages 4–7.

The Global Deterioration Scale has played an important role in clinical care by focusing attention on the level of patient decline, but the scale itself has significant conceptual and methodological limitations. Reisberg et al. (8) reported that the scale was developed using what they described as "systematic phenomenologic observation" of the nature of symptoms in patients with Alzheimer's disease as well as in other individuals with age-associated memory impairment. There was no clear discussion of the psychometric methods used to relate the seven stages to the clinical parameters specified in the scale. Furthermore, the clinical description for each stage uses different units of observations for behavioral dysfunction. The Global Deterioration Scale is based on implicit assumptions about the linearity, temporality, and interdependencies of cognitive, functional, and behavioral impairment as well as neuroanatomical integrity. These assumptions require empirical evidence to support the Global Deterioration Scale's descriptions of incidence and changes in behavioral dysfunction across the seven stages.

The development of the Global Deterioration Scale relied heavily on correlations between progression on the scale and brain imaging data in a sample of 43 patients and seven other persons who underwent positron emission tomography (PET) scans of their brains (7, 8). In addition, Global Deterioration Scale scores were correlated with several cognitive domains and functional abilities derived from tests with 54 patients and from interviews with 36 patients concerning adaptation.

The Global Deterioration Scale makes predictions about patients' ability to function, as reflected in activities of daily living (e.g., bathing, dressing) and instrumental activities of daily living (e.g., handling money, using a telephone), as well as psychiatric morbidity, on the basis of progressive cognitive loss. In general, the scale postulates that significant functional and psychiatric disability does not occur until the latter stages of dementia. It specifies that psychiatric symptoms such as flattening of affect and anxiety occur in stage 4 and that it is not until stage 6 that pervasive personality and emotional changes occur. Progression of functional impairments is described in the Global Deterioration Scale with uneven detail, but stage 6 is described as the period when some assistance is needed with activities of daily living. The scale states that no assistance with toileting is needed in stage 5 but that patients will have difficulty choosing clothes. In the final stage, patients are described as incontinent of urine, needing assistance with toileting and eating, and losing the ability to walk.

The empirical literature on Alzheimer's disease as well as consensus diagnostic criteria for the disease suggest that psychopathology and functional impairment are prevalent conditions (*DSM-III-R*, 2, 3, 6, and unpublished work of D. Cohen et al.). Therefore, we hypothesized that psychopathology and functional impairment would occur in patients at all stages of the Global Deterioration Scale and that significant differences in adjacent stages would occur before the transition from stage 5 to stage 6 as predicted by Reisberg et al. (7).

**TABLE 1. Ranges of Scores on the Mini-Mental State Examination Used in This Study to Assign Patients With Alzheimer's Disease to Global Deterioration Scale Stages 2–7 and Ranges Used by Reisberg et al. (11)**

| Stage on Global Deterioration Scale | Range of Scores on Mini-Mental State: Reisberg et al. Study | Range of Scores on Mini-Mental State: This Study |

| 4 | 16–23 | 17–20 |
| 5 | 10–19 | 11–16 |
| 6 | 0–12 | 1–10 |
| 7 | 0 | 0 |

## METHOD

We used a set of data from a registry of patients with Alzheimer's disease to evaluate the Global Deterioration Scale in a large sample. The data include sociodemographic, clinical, and psychosocial information on dementia patients enrolled at six medical centers in three states between May 1988 and May 1989 (9). The clinical centers enrolled patients 40 years of age or older who were living in the community and who had been diagnosed as having Alzheimer's disease or a related disorder between 1987 and 1989. The Alzheimer's disease patient registry, also known as the Prototype Alzheimer Collaborative Team, was funded as part of a cooperative agreement by the National Institutes of Health and the National Institute on Aging to test the feasibility of enrolling large numbers of patients with dementia at diverse clinical sites in a registry for research on Alzheimer's disease.

The case registration and data collection methods as well as a sociodemographic profile of the entire Prototype Alzheimer Collaborative Team population have been described elsewhere (9). Briefly, a central Data Coordinating and Analysis Center in the School of Public Health at the University of Illinois at Chicago registered patients with Alzheimer's disease and related disorders enrolled at six medical sites in the Miami, Milwaukee, and Chicago areas. The sample for this study included 324 of these patients. Three hundred twenty of them met the *DSM-III-R* or NINCDS-ADRDA (2) criteria for Alzheimer's disease, and an additional four patients were given the diagnosis of primary degenerative dementia according to *DSM-III*. Subjects included in this analysis also had to have no missing data for sociodemographic, psychiatric, mental status, and functional status variables recorded in the case enrollment forms.

Two procedural decisions were made prior to the data analyses for this report. First, we established ranges of nonoverlapping scores on the Mini-Mental State examination (10) as the criteria for defining the seven stages. These ranges, identified in table 1, were modified from

**TABLE 2. Characteristics of 324 Patients With Alzheimer's Disease Classified According to Stages on the Global Deterioration Scale**

| Stage on Global Deterioration Scale | N | Age (years) |  | Sex Ratio (M/F) | Duration of Illness (years)[a] |  |
|---|---|---|---|---|---|---|
|  |  | Mean | SD |  | Mean | SD |

[b] Significant difference between stage 3 and stage 4 ($\chi^2$=12.15, df=2, p=0.002).

the overlapping ranges of the Global Deterioration Scale published in 1986 (11). Although Reisberg et al. (11) have argued that mental status scores are not the sole criteria for assignment to the stages of the Global Deterioration Scale, they defined these stages in cognitive terms (7, 8, 11). It was necessary to eliminate overlapping scores to establish the frequency distributions of the noncognitive variables. Second, we chose to examine stages of the Global Deterioration Scale only among Prototype Alzheimer Collaborative Team registry cases in which the patients met diagnostic criteria for probable or possible Alzheimer's disease according to the NINCDS/ADRDA criteria (2), primary degenerative dementia of the Alzheimer type according to *DSM-III-R*, or primary degenerative dementia according to *DSM-III*. Table 2 presents characteristics of the sample classified into stages 2–7, since stage 1 refers to no cognitive decline.

Data analysis consisted of 1) descriptive statistics on the frequency of occurrence of psychiatric morbidity and impairment in the six activities of daily living rated in the Prototype Alzheimer Collaborative Team cases and 2) logistic regression (12), with individual psychiatric symptoms and functional impairment as independent variables, to test for significant changes between stages of the Global Deterioration Scale. For each symptom or impairment category, logistic regression was used to test differences in prevalence between adjacent pairs of stages. If onset of a given symptom is associated with stage k, then the prevalence of that symptom at stage k should be significantly higher than at stage k–1. The differences between adjacent stages 2 through 7 were coded as five indicator variables: $X_3$ was 1 if the stage was 3 or more and 0 if it was otherwise, $X_4$ was 1 if the stage was 4 or more and 0 if it was otherwise, and so on up to $X_7$, which was 1 if the stage was 7 and 0 if it was otherwise. With these five indicator variables as predictors and the logit of symptom or functional impairment status as the outcome, the coefficient $\text{beta}_k$ for $X_k$ is equal to the log odds of prevalence in stage k versus prevalence in stage k–1. If $\text{beta}_k=0$, then the prevalence in stage k is equal to the prevalence in stage k–1. The null hypothesis, $\text{beta}_k=0$, was tested for each coefficient in each model by a chi-square test with one degree of freedom.

## RESULTS

As shown in table 3, 52.0% of the Alzheimer's disease patients at stage 2 displayed psychopathology, and 32.0% had two or more symptoms. By stage 6, 77.1% had psychiatric morbidity, but the significant increase between adjacent levels occurred earlier than postulated by the Global Deterioration Scale, i.e., between stages 3 and 4, not stages 5 and 6.

The results of logistic regression procedures to test significant differences in the prevalence of nine psychiatric symptoms by Global Deterioration Scale stage are reported in table 4. Although patients at all stages displayed agitation, a statistically significant increase in agitation occurred between stages 3 and 4. The prevalence of hallucinations and insomnia also increased significantly between stages 3 and 4.

Impairment in activities of daily living was observed in patients at all stages of the Global Deterioration Scale. Although functional impairments were more severe in later stages, 20% of the patients in stage 2 had at least one impairment in activities of daily living. This doubled to 40% for patients in stage 3 and continued to increase to 51% for those in stage 4, 65% in stage 5, 77% in stage 6, and 100% in stage 7. As shown in table 5, the percentage of patients with difficulties in bathing changed significantly from stage 3 to stage 4 and from stage 5 to stage 6. The most significant change in difficulties in dressing on adjacent stages of the Global Deterioration Scale occurred between stages 4 and 5; however, fully one-fifth of the patients were impaired on this variable in stage 3. The most significant shifts for eating, transferring from bed to chair, and walking occurred between stages 5 and 6 and stages 6 and 7.

## DISCUSSION

Since its publication in 1982, the Global Deterioration Scale has been widely used to stage Alzheimer's disease. It was developed by using primarily a conceptual approach, rather than psychometric and statistical methods, to describe cognitive and noncognitive characteristics associated with the course of this disease and related disorders. A number of assumptions were made concerning the occurrence, rate of change, and interrelationships of cognitive impairment, behavioral dysfunction, impairment in activities of daily living, and psychiatric symptoms.

Our results show that significant psychopathology occurs at earlier stages of the Global Deterioration Scale than predicted by Reisberg et al. (7). Although the scale specifically states that no assistance with toileting and eating is needed until stage 6, 21.1% of the patients in stage 5 had problems with toileting and 10.8% had problems with eating. The most significant changes in problems with bathing occurred between stages 3 and 4 as well as between stages 5 and 6. Bathing is not referred to explicitly in the Global Deterioration Scale, but even if it is classified under the general category of "some assistance with activities of daily living" in stage 6, significant change occurred earlier than predicted. Although the Global Deterioration Scale specifically states that no assistance is needed for eating and toileting in stage 5 but is needed in stage 7, these results show an earlier shift.

Our results support one of the basic assumptions underlying the Global Deterioration Scale and all other clinical staging instruments, i.e., that patients with Alzheimer's disease become progressively worse as a natural course of the disease. Indeed, the most useful rating scales for staging Alzheimer's disease rely heavily on cognitive measures (13–15).

It is clear from our results that psychiatric pathology and functional impairment associated with Alzheimer's disease occur sooner than predicted by the Global Deterioration Scale and that the rate of change is different from that specified in the instrument. Our results also have broader implications for understanding Alzheimer's disease. A wide range of psychiatric symptoms may be seen quite early in the disease. Even Alois Alzheimer's initial report (16) described a number of psychiatric symptoms in his 51-year-old patient, including strong feelings of jealousy as the earliest presentation of the disorder. Although cognitive deficits are primary symptoms, they rarely occur without substantial dysfunction in other areas.

The Global Deterioration Scale has been reported to have good interrater reliability, ranging from 0.82 to 0.92 (13, 17, 18). Its validity is difficult to evaluate without prospective longitudinal clinical studies with standardized assessments of the cognitive and noncognitive variables, followed by neuropathological confirmation of the diagnosis of Alzheimer's disease. Validation studies reported to date have relied on correlations of assigned stages of the Global Deterioration Scale with clinical, psychometric, and imaging (i.e., CT and PET scan) variables (7, 8, 17–19). These, however, are indirect measures of validity.

The authors of the Global Deterioration Scale are probably correct in asserting that ordinal progression of functional decline may be affected by coexisting pathology. However, they implicitly postulate a single, relatively consistent progression of decline in Alzheimer's disease without empirically verifying this hypothesis. An example of the difficulties that may occur in the utilization of the scale is the assumption, according to the scale, that symptoms of Alzheimer's disease are not detectable in stage 2 and that stage 3 defines incipient Alzheimer's disease (7, 8, 11, 19). The results in this report demonstrate that patients with clinically diagnosed disease and mild impairment according to the Mini-Mental State examination can be classified in stage 2, and by that stage they already show significant psychopathology.

The use of the Global Deterioration Scale as a global staging instrument carries with it the subtle hazard that because the scaled score provides information in a quasi-mathematical form, it can appear to convey more information about the patient's condition than it actually does. In addition, it presumes the homogeneity of Alzheimer's disease, whereas a growing literature supports the hypothesis that it may be a heterogeneous disease (20–24).

Since staging of Alzheimer's disease by using the Global Deterioration Scale implies an overall clinical state, which in turn is a basis for examining other clinical variables, it is important to recognize that these variables array themselves differently than posited in the Global Deterioration Scale. The use of separate instruments to describe cognitive status, psychiatric symptoms, and functional status (10, 14, 25) may be the most accurate way to describe the illness until better multidimensional scales are developed.

# Treatment of Imipramine-Resistant Recurrent Depression, IV: A Double-Blind Crossover Study of Tranylcypromine for Anergic Bipolar Depression

Michael E. Thase, M.D., Alan G. Mallinger, M.D., Damien McKnight, B.S.,
and Jonathan M. Himmelhoch, M.D.

Objective: *Few trials of monoamine oxidase inhibitors (MAOIs) in tricyclic-resistant depression have had double-blind conditions. In the authors' previous double-blind comparison of tranylcypromine and imipramine in anergic bipolar depression, tranylcypromine was significantly more effective. This investigation was a crossover study of nonresponders in the initial study.* Method: *The subjects were 16 outpatients with anergic bipolar depression. Fourteen had not responded to 4 weeks of treatment with at least 30 mg/day of tranylcypromine or 150 mg/day of imipramine, and two patients were crossed over because of intolerable side effects from the initial drug. The crossover medication was prescribed as in the initial double-blind study.* Results: *Twelve patients were crossed over from imipramine to tranylcypromine; nine of them responded to tranylcypromine. Highly significant improvements were documented on the Hamilton, Beck, and Pittsburgh Reversed Vegetative Symptom Scales. Four patients were switched from tranylcypromine to imipramine, but only one responded.* Conclusions: *The high rates of response to tranylcypromine in both the initial and crossover double-blind studies document the efficacy of MAOI treatment for anergic bipolar depression. Moreover, the results further illustrate the utility of MAOIs in tricyclic-resistant depressions.*

(Am J Psychiatry 1992; 149:195–198)

The effectiveness of monoamine oxidase inhibitors (MAOIs) for tricyclic-resistant depressions has been suggested by a number of studies (1–6). Most investigators (1–6) have found response rates of at least 50%, and up to 80% treatment efficacy was found when the MAOI was used in combination with lithium salts (1, 2) or was given to patients who manifested atypical symptoms or reversed neurovegetative signs (5, 6). Despite such apparent consistency across research sites, to our knowledge only one trial using MAOIs for treatment-resistant depression has been conducted under double-blind conditions (5). Thus, it is conceivable that the enthusiasm of the treating clinicians for this rather controversial family of antidepressants may have inflated the response rate. Further, the one published study employing a randomized, double-blind design (5) specifically dealt with nonbipolar patients who had milder, more chronic depression, so its findings may not be generalizable to populations with more episodic or severe illness, such as patients with bipolar affective disorder.

In a previous report (7), we documented that tranylcypromine was significantly more effective than imipramine in a randomized, double-blind study of the acute treatment of 56 patients with anergic bipolar depression. Patients who did not respond to the initial treatment in that protocol were, after an appropriate washout, treated with the other study drug. We now report the results of this double-blind crossover trial.

## METHOD

Both our methods for recruitment and assessment of subjects and the results of double-blind treatment in the initial outpatient study of anergic bipolar depression have been reported elsewhere (7). To briefly summarize, potentially eligible patients were evaluated with the following operationalized criteria (8) for an episode of anergic bipolar depression: 1) bipolar affective disor-

der with a current episode of major depression according to the criteria of *DSM-III* and the Research Diagnostic Criteria (RDC) (9), 2) a total score of 15 or higher on the first 17 items of the Hamilton Rating Scale for Depression (10), 3) the clear-cut presence of fatigue and/or volitional inhibition, 4) predominant psychomotor retardation as manifested by a score of 2 or higher on item 8 of the Hamilton scale, and 5) at least one reversed neurovegetative symptom: hypersomnia (1 or more hours of sleep each night beyond normal sleep requirement) and/or weight gain (2.2-kg or greater increase in weight during current episode). We also confirmed the severity of past manic or hypomanic episodes by consulting an independent source (e.g., family member or medical record) to establish the RDC diagnosis of bipolar I or bipolar II subtype. These diagnoses were made with acceptable interrater reliability (7). All patients provided written consent for research participation.

During acute treatment, the patients were seen weekly by a nurse clinician and psychiatrist. All medication capsules appeared identical and contained inert placebo, 10 mg of tranylcypromine, or 50 mg of imipramine. The patients were given two medication containers at each visit: one was labeled "morning medication" (containing either active tranylcypromine or placebo, to be taken at 7:00 and 11:00 a.m.), and the other was labeled "evening medication" (containing either active imipramine or placebo, to be taken at 4:00 p.m. and bedtime). The initial treatment was 20 mg/day of tranylcypromine or 100 mg/day of imipramine. The dose was advanced routinely by one unit of active drug (i.e., 10 mg of tranylcypromine or 50 mg of imipramine) on the 4th day of the protocol. Thereafter, the daily dose was increased by one active drug unit each week until clinical response occurred, up to a maximum dose of six active drug units per day. The treating clinicians decreased the dose or did not increase it at the maximum rate if significant side effects occurred. A patient was considered a nonresponder only if he or she completed at least 4 weeks of treatment and reached at least 30 mg/day of tranylcypromine or 150 mg/day of imipramine.

Depressive symptoms were assessed at each visit with the patient-rated Beck Depression Inventory (11) and the clinician-rated 17-item Hamilton scale, Clinical Global Impression (CGI) (12), and Pittsburgh Reversed Vegetative Symptom Scale (6). The Reversed Vegetative Symptom Scale is an 8-item supplement to the Hamilton scale that measures features of an anergic depressive state (it is available from Dr. Thase on request). It is constructed to correspond exactly with the format of the original Hamilton scale and to explicitly balance the items rating more classically melancholic symptoms with a comparable number of items covering hypersomnia, hyperphagia, and weight gain. In addition, the Reversed Vegetative Symptom Scale provides items covering volitional inhibition, motor retardation, and diurnal mood variation.

After completion of the acute treatment trial, patients

who had failed to meet all three of the following criteria were withdrawn from study medication: 1) CGI score indicating moderate or marked improvement (i.e., +2 or +3), 2) at least a 50% reduction in Hamilton scale score, and 3) Hamilton scale score less than 10. After a 1-week medication-free interval, 14 patients still did not meet these criteria for response and began treatment with the other study medication. Two additional patients were crossed over without having received adequate trials of study medication because they developed severe, intolerable side effects while taking the initial drug. Characteristics of the 16 crossover patients are summarized in table 1. The crossover medication was prescribed exactly as in the original trial. The double blind was maintained throughout this process, and all patients continued to follow a low-tyramine diet.

Upon disclosure of the medications, we found that 10 patients were imipramine nonresponders who had been crossed over to tranylcypromine and only four were tranylcypromine nonresponders who had been switched to imipramine. This discrepancy was due to the greater efficacy of tranylcypromine in the original study (7). Further, both patients who were crossed over because of severe side effects during the initial treatment phase had been taking imipramine. Therefore, the data analysis we had planned was not possible because of the small number of nonresponders crossed over from tranylcypromine to imipramine. The clinical outcome of these four patients treated with imipramine will be summarized descriptively. Improvements during crossover tranylcypromine treatment of the remaining 12 patients on the depression measures (Hamilton scale, Reversed Vegetative Symptom Scale, and Beck scale) were analyzed with paired t tests (i.e., pretreatment score versus posttreatment score). The responses during the initial treatment with imipramine and the subsequent crossover treatment were also compared with paired t tests (i.e., percent change with drug 1 versus percent change with drug 2). Finally, for comparison, the outcome of the 26 patients who received adequate trials of tranylcypromine in the initial study (7) was contrasted with the response of the tranylcypromine crossover group.

## RESULTS

Nine (75%) of the 12 patients who had originally failed to benefit from imipramine responded to tranylcypromine crossover treatment. Two of the three nonresponders during crossover treatment were not able to tolerate tranylcypromine doses higher than 30 mg/day. During the 6 weeks of tranylcypromine crossover treatment, highly significant improvements on all three dependent measures were noted (table 2). The improvements in depression scores during tranylcypromine crossover treatment also were significantly greater than the improvements of these same 12 patients during the preceding imipramine treatment phase. The response to tranylcypromine during crossover treatment also was comparable to the results observed in the 26 patients treated with tranylcypromine in the initial study (7). For example, categorical response was almost identical in the two tranylcypromine treatment groups (75% and 81%), as was percent improvement on the Hamilton scale (t=0.60, df=36, n.s.). Two of the patients who responded to tranylcypromine during crossover treatment developed hypomania during a 12-week continuation treatment period.

Reanalyses of response to tranylcypromine crossover treatment after removal of the two patients who had not tolerated imipramine in the original trial did not alter any of the findings of significance. Of the 10 patients who had received at least 4 weeks of imipramine treatment at doses of 150 mg/day or higher in the initial study, eight (80%) responded to tranylcypromine crossover treatment.

One of the four patients crossed over from tranylcypromine to imipramine responded. Two patients withdrew from treatment prematurely because of side effects, and the remaining patient cycled into a mixed manic state after 4 weeks of therapy with imipramine at 150 mg/day.

## DISCUSSION

In previous "open-label" studies, our group has found that both lithium augmentation (13) and treatment with MAOIs (6) are effective second- and third-line strategies for imipramine-resistant patients with recurrent unipolar depression. In the MAOI study, improvement was most robust in unipolar patients with anergia, psychomotor retardation, and/or reversed neurovegetative features. The current report adds to the literature on tricyclic-resistant depression by documenting the efficacy of MAOI treatment for a group of patients with anergic bipolar depression. Further, to our knowledge, it is only the second trial to use a double-blind, crossover design to study MAOI treatment of tricyclic-resistant depression (cf. McGrath et al. [5]).

Our subjects did not include bipolar patients with more agitated symptoms and were not receiving concurrent lithium therapy. It is conceivable that cotherapy with lithium salts could have enhanced response to imipramine in both the original and crossover protocols, whereas inclusion of patients with agitated depression might have dampened the rate of response to tranylcypromine. Further, it is unclear whether or not anergically depressed, imipramine-resistant patients could have been treated as effectively with a nonsedating tricyclic (e.g., desipramine) or a newer cyclic antidepressant (e.g., bupropion or fluoxetine) as they were with tranylcypromine. Given the inconveniences and risks associated with MAOI treatment, as well as many clinicians' continued preference for tricyclics in the treatment of bipolar depression (14), it seems likely that lithium augmentation will remain a reasonable initial strategy for treatment of tricyclic-resistant bipolar depression. The specific utility of lithium augmentation for psychotic bipolar depression was suggested by the findings of Price et al. (15). Moreover, in the great majority of cases, it is necessary to start lithium treatment after successful antidepressant therapy of bipolar depression.

Nevertheless, it is striking that the response rate and degree of improvement in the current study of imipramine-resistant anergic bipolar patients are so similar to the results of the original study (7). These findings also correspond closely with those from our group's previous open-label study of MAOI treatment of imipramine-resistant patients with unipolar depression (6) and the McGrath et al. crossover study of phenelzine treatment of patients with atypical depression (5). When considered together, the results of these four trials provide compelling evidence that 70%–80% of patients with fatigue, psychomotor retardation, and/or reversed neurovegetative features respond well to MAOIs, even if they first fail to benefit from treatment with standard tricyclics.

# Lack of Association Between Dopamine $D_1$ and $D_2$ Receptor Genes and Bipolar Affective Disorder

Markus M. Nöthen, M.D., Jeanette Erdmann, M.Sc., Judith Körner, M.D., Mario Lanczik, M.D., Jürgen Fritze, M.D., Rolf Fimmers, Ph.D., David K. Grandy, Ph.D., Brian O'Dowd, Ph.D., and Peter Propping, M.D.

*Fifty-six patients with bipolar affective disorder and 69 healthy control subjects were tested for association of restriction fragment length polymorphism alleles at the dopamine $D_1$ and $D_2$ receptor loci. No significant associations were found; thus, the hypothesis that a single mutant form of either receptor gene is responsible for the phenotype of patients with bipolar affective disorder was not supported.*

(Am J Psychiatry 1992; 149:199–201)

Human dopaminergic neurons are involved in the control of hormone secretion, voluntary movement, and emotional behavior. These effects are mediated by dopamine $D_1$ and $D_2$ receptors that stimulate and inhibit, respectively, the enzyme adenylate cyclase. Dopamine antagonists display antimanic properties and, conversely, dopaminergic drugs can provoke a switch to mania. Thus, an involvement of dopaminergic receptors in the pathophysiology of bipolar affective disorder would seem evident.

The human $D_1$ and $D_2$ receptor genes have recently been cloned and assigned to the chromosomal regions 5q31–34 and 11q22–23, respectively (1–5). Sometimes chromosomal aberrations provide additional clues to where a gene may reside. In a recently reported family, a balanced 9/11 chromosomal translocation cosegregated with bipolar affective disorder; the breakpoint on chromosome 11 was at 11q22.3 in close proximity to the $D_2$ receptor gene (6).

True association may occur for two reasons: 1) there is strong linkage disequilibrium between a disease-causing locus and the locus under study (recombination fraction <1%), and 2) the marker locus itself contributes to the pathogenesis of the illness (7). In a number of complex disorders, association studies have been successfully performed. In narcolepsy, for example, an almost 100% association with the human lymphocyte antigen (HLA) DR2 allele was found. In affective disorders, studies focused on blood group and HLA antigens; results were either negative or inconsistent. Recent advances in molecular biology and the increasing availability of polymorphic DNA segments as markers have greatly expanded the potential utility of these markers in association studies. Genes that, by evidence of biochemical or pathophysiological abnormalities in the illness under study, possibly contribute to the etiology of the illness serve as candidate genes. Usually, a candidate gene for the disease is selected and a nearby restriction fragment length polymorphism (RFLP) is used as a tool to compare patients and control subjects. The association approach is different from linkage studies, where cosegregation of a marker trait and the disease is examined in families. A major advantage of association studies is that no assumptions have to be made about the mode of inheritance, penetrance, and age at onset of the disease.

Recently, the first association of an RFLP with bipolar affective disorder was reported for the tyrosine hydroxylase gene in patients and control subjects in France (8). However this association could not be replicated in a German sample (9). To look for a possible association between RFLP alleles detected by $D_1$ and $D_2$ DNA probes and bipolar affective disorder, we examined a series of unrelated patients with bipolar illness and a group of control subjects.

## METHOD

We tested 56 patients with bipolar affective disorder ascertained at random from admissions to the Psychiatric Clinic, University of Würzburg, Germany. Thirty-one of the patients were female and 25 were male. All

**TABLE 1. Dopamine $D_1$ and $D_2$ Receptor Genotypes and Allele Frequencies in Patients With Bipolar Affective Disorder and Healthy Control Subjects**

| | $D_1$ Receptor | | | | | | $D_2$ Receptor | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Genotype[a] | | | Allele Frequency[b] | | Estimated SE | Genotype[c] | | | Allele Frequency[d] | | Estimated SE |
| Group | A1/A1 | A1/A2 | A2/A2 | $a_1$ | $a_2$ | | B1/B1 | B1/B2 | B2/B2 | $b_1$ | $b_2$ | |
| Patients (N=56) | 1 | 13 | 42 | 0.13 | 0.87 | 0.03 | 3 | 17 | 36 | 0.21 | 0.79 | 0.04 |
| Control subjects (N=69) | 1 | 19 | 49 | 0.15 | 0.85 | 0.03 | 5 | 26 | 38 | 0.26 | 0.74 | 0.04 |

[a] A1 allele corresponds to absence of EcoRI restriction site, and A2 to its presence.

[b] $\chi^2$=0.17, df=1, p=0.68.

[c] B1 and B2 refer to absence and presence, respectively, of TaqI restriction site polymorphism.

[d] $\chi^2$=1.05, df=1, p=0.30.

suffered from bipolar disorder that had been diagnosed according to the *DSM-III* criteria. Diagnostic assessments were based on clinical interviews by an experienced psychiatrist, review of case notes, and family history data. Twenty-nine patients had family histories of affective disorder.

Sixty-nine persons were tested as control probands. They were recruited from among medical students and laboratory staff members. Persons with family histories of psychiatric illness were excluded. The female-to-male ratio in this group was 34:35.

All subjects examined (patients and control subjects) were native Germans. All gave informed consent.

Venous blood samples, with EDTA as the anticoagulant, were drawn from all probands. Genomic DNA was extracted from buffy coat preparations by salting out with saturated sodium chloride solution and then digested with restriction enzymes. DNA fragments were subjected to electrophoresis on 0.7% agarose gel and transferred to nylon filters. DNA probes were labeled with $[\alpha\text{-}^{32}\text{P}]$dCTP by the random primer method and hybridized to the blots. Filters were washed at a final stringency of 0.1×standard saline citrate at 65 °C and exposed to Kodak XAR-5 film with image intensifier for 1–4 days at –70 °C to produce autoradiographs.

A 3-kilobase (kb) fragment of a human $D_1$ DNA clone containing on a single exon the entire coding region of the $D_1$ receptor detects a 6.8-kb and a 10.5-kb band RFLP in EcoRI digests. An 18-kb fragment of a human $D_2$ DNA clone detects a 2.2-kb and a 9.0-kb band RFLP in TaqI digests. This fragment comprises the sequence coding the 63 amino acid residues of the C terminus of the $D_2$ receptor, the 3′ untranslated region of the receptor mRNA, and 3′ flanking sequences.

## RESULTS AND DISCUSSION

To test for the general involvement of the dopamine $D_1$ and $D_2$ receptor genes in bipolar affective disorder, we determined RFLP genotypes in the patients and the control subjects. Genotypic frequencies were not found to differ significantly from those expected according to the Hardy-Weinberg equilibrium (10).

When the allele frequencies of the two test groups were compared, there were no significant associations between affected status and allele frequencies at the two dopamine receptor loci (table 1). The allele frequencies in both of the groups were similar to those reported for unrelated healthy Caucasians (2, 5). For the EcoRI site, the comparison between patients and control subjects, expressed as a relative risk, was 1.16 (p=0.68). The relative risk for the TaqI site was 1.37 (p=0.30). To demonstrate the power of the study under the given sample size, we included a power calculation. Fixing the allele frequencies for the control subjects at 0.15 for the A1 allele of the $D_1$ receptor RFLP and at 0.26 for the B1 allele of $D_2$, the power to detect an association is >0.80 for allele $a_1$ frequencies$\leq$0.04 ($b_1\leq$0.12) and $a_1$ frequencies$\geq$0.30 ($b_1\geq$0.43) in the patient group.

Since the genetic load may be higher in patients with family histories of affective disorder, we subdivided the patient group on the basis of having no relative with affective disorder (N=27) or at least one relative with affective disorder (N=29). The allele frequencies of the two dopamine receptor RFLPs for these two groups of bipolar patients were compared to the frequencies in the control group (data not shown). No significant differences between the two patient groups and the control group were found.

The results of this study do not support the hypothesis that a single mutant form of either the dopamine $D_1$ or the dopamine $D_2$ receptor gene is responsible for the phenotype of all or an appreciable proportion of patients from the general population who are suffering from bipolar affective disorder.

# Controlled Investigation of the Amobarbital Interview for Catatonic Mutism

W. Vaughn McCall, M.D., Frank E. Shelp, M.D., and William M. McDonald, M.D.

---

*Objective: Clinical reports over the last 60 years suggest that the amobarbital interview is effective in relieving catatonic symptoms. This has never been substantiated with methodologically sound trials. The authors postulated that a randomized blind comparison of intravenous amobarbital and saline would demonstrate the superiority of amobarbital in relieving catatonic mutism. Method: The subjects were 20 inpatients with catatonic mutism. They were randomly assigned to either saline (N=10) or a 5% amobarbital solution (N=10), and the infusions were administered intravenously at a rate of 1 cc/min or less over 10 minutes by a blinded physician. A second blinded physician administered a semistructured interview during the infusion to control for the effect of suggestion. A third blinded physician rated patient responsiveness, reactivity, and arousal. Any patient who was unresponsive to the initial infusion was crossed over to the other infusion. Interviews were videotaped for determination of interrater reliability. Results: In the initial infusions, six of 10 patients responded to amobarbital and zero of 10 responded to saline. Four of the saline nonresponders responded when given amobarbital. Response was evident by the 4th minute of the amobarbital infusion. Interrater reliability was high. The responders and nonresponders differed significantly in the variance of the weight-adjusted amobarbital dose, and the responders tended to be older and female. Conclusions: Intravenous amobarbital is superior to saline in relieving catatonic mutism, although only 50% of these patients responded. The nonresponders were distinguished from the responders by a greater variance in the weight-adjusted dose of amobarbital.*

(Am J Psychiatry 1992; 149:202–206)

---

Sixty years ago Bleckwenn (1, 2) proposed the administration of intravenous amobarbital as a means of relieving acute symptoms in psychiatric patients. Since that time amobarbital-facilitated interviews have become popularly known as "Amytal interviews" (2) and have been credited with the power to assist in retrieval of repressed memories (anamnesis), production of blocked affects (abreaction), and the relief of conversion and catatonic physical symptoms (3). To our knowledge, however, no randomized and blinded studies have substantiated the superiority of amobarbital over a control solution.

Two studies using a saline control (4, 5) strongly suggested that amobarbital is superior in relieving catatonic symptoms, but these studies did not use random assignment or blindly made ratings. The only blinded, randomized, and controlled study of the amobarbital interview in psychotic and severely disturbed patients (6) failed to show that amobarbital is more effective than a control solution in revealing new symptoms or clarifying the differential diagnosis. A series of methodologically sound investigations in "psychoneurotic" patients (7) also failed to establish the superiority of amobarbital in producing anamnesis/abreaction.

We conducted a randomized, blinded, and controlled investigation of the amobarbital interview with catatonic patients. We hypothesized that intravenous amobarbital would be superior to saline in relieving catatonic mutism. Mutism was chosen as a target symptom because 1) it is among the most frequent of catatonic signs (8), 2) we felt it could be reliably identified by independent examiners, 3) previous anecdotal reports (4) suggested that mutism is the catatonic symptom least vulnerable to placebo response, and 4) because of the variable presentations of catatonia, we felt it was

important to homogenize our study group with one unifying symptom.

## METHOD

### *Subjects*

Of the 30 patients screened for this study, 10 were mute at the time of admission but became at least partially verbal on the wards or during preparation for the amobarbital interview, so they were not included in the study. Twenty patients completed the study. Their mean age was 45.4 years (SD=15.4), and there were 10 men and 10 women. All were inpatients and were persistently and totally mute; none of the patients made intelligible verbal or nonverbal responses or movements. For 18 patients, mutism was an acute symptom that was present at admission and had lasted 1–5 days, and these patients participated in the study during the first week of hospitalization. The other two patients had been mute and hospitalized for 4–6 months. Sixteen of the patients were identified and studied at a state psychiatric hospital, and the other four patients were identified at a university hospital. Admission diagnosis was not considered in selecting patients for the study; we required only catatonic mutism.

Acute mutism may be related to neurological or psychiatric conditions (9). Even among psychiatric conditions, mutism does not necessarily indicate catatonia, so, in addition to mutism, we required other signs of catatonia. All of the patients were in a motionless stupor. Twelve demonstrated rigidity, eight were negativistic, and one had catalepsy. None of the patients had a prior documented episode of catatonia. Catatonic symptoms can be evanescent, so, to reduce the possibility of placebo response, we required that our subjects demonstrate persistent mutism. Persistent mutism was defined as being 1) noted in the admission mental status examination, 2) still present when the patient was screened by one of us in the first week and consistently documented in the progress notes, 3) still present when the patient was taken to a distant examination room and an intravenous line was inserted.

Each patient was examined by a neurologist at the time of the interview (W.M.M.) and was found to be free of localizing neurologic signs. No patient had a history of head trauma, epilepsy, or other primary brain disease. Ten patients underwent routine EEGs before the amobarbital interview, and all EEG results were nonsignificant.

### *Consent*

Informed consent was obtained from the guardians of the four patients who had previously been judged incompetent in legal proceedings. The remaining patients were unable to give consent by virtue of their illness. This issue has been recently addressed in similar circumstances (10). In our study, the investigational review board of the university hospital required a relative's consent for the procedure. A second consent for use of the acquired data was obtained from the patient later, when competency had been regained with treatment.

### *Procedure*

Each patient was taken to a private area of the hospital, and an intravenous line was inserted in the patient's arm. The presence of catatonic mutism was again confirmed by two psychiatrists (W.V.M., F.E.S.). A psychiatrist (F.E.S.) made baseline recordings of the patient's level of awareness and cooperation. A second psychiatrist (W.V.M.) conducted the interview, and a third physician (W.M.M.) administered the intravenous infusion. A nurse prepared a 10-cc syringe of 5% amobarbital (which is indistinguishable from saline). A syringe containing either saline or amobarbital solution was given to the first three physicians, who remained blind to the identity of the solution. The nonblind nurse left the room and did not participate in any aspect of amobarbital administration, interviewing, or patient ratings. A counterbalanced design allowed for 10 patients to initially receive amobarbital and 10 to receive saline. We followed Bleckwenn's original protocol of giving no more than 1 cc/min (1, 2). The physician administering the infusion was encouraged to give 1 cc/min unless the patient was obviously showing a beneficial response or was going to sleep. The exact rate of infusion, however, was at the discretion of the physician administering the solution. Each infusion was given over 10 minutes.

During a clinical amobarbital interview, the physician generally gives the patient suggestions and encouragement. These factors could be more important than the amobarbital in relieving catatonic mutism, so we used a semistructured interview created for this study. The interview consisted of 10 statements of assurance and questions about orientation that were made to each patient during each 10-minute infusion at a tempo determined by the interviewer (appendix 1). The interviewer was allowed to break away from the semistructured interview if the patient responded to a particular line of questioning.

The physician rater assessed the patient's level of arousal and reactivity during each minute of the infusion by using a 5-point scale created for this study (appendix 2). Also, at the end of the 10-minute infusion the rater judged each patient's global response to the infusion on a 5-point improvement scale (appendix 3). All ratings were performed by the same rater. Only patients judged to have a "definite and sustained" or "dramatic" improvement were deemed "responders." Patients with equivocal or transient changes were designated "nonresponders."

At the end of the first 10-minute infusion, any patient who had failed to respond was immediately given another interview with whichever solution was not given in the first infusion. Because no patient responded to saline, every patient thus received amobarbital. As dur-

**TABLE 1. Characteristics of Patients With Catatonic Mutism Who Did or Did Not Respond to Amobarbital Interviews**

| | Age (years) | | Sex | | Affective Disorders | | Body Weight (kg) | | Amobarbital Dose | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | | | | | | Total (mg) | | Weight-Adjusted (mg/kg) | | |
| Group | Mean | SD | M | F | Yes | No | Mean | SD | Mean | SD | Mean | SD | Variance[a] |
| Responders (N=10) | 51.6 | 15.9 | 4 | 6 | 7 | 3 | 63 | 15 | 305 | 91 | 4.9 | 1.2 | 1.3 |
| Nonresponders (N=10) | 39.3 | 12.9 | 6 | 4 | 5 | 5 | 74 | 22 | 355 | 152 | 4.6 | 2.3 | 5.4 |
| Total (N=20) | 45.4 | 15.4 | 10 | 10 | 12 | 8 | 70 | 17 | 330 | 125 | 4.8 | 1.8 | 3.2 |

[a] t=4.1, df=18, p<0.03.

ing the first interview, ratings were systematically carried out every minute and at the end of 10 minutes. The interviewer again used the semistructured interview. The patient's weight, the psychotropic drugs administered over the previous 24 hours, the total dose of amobarbital given, and the discharge diagnosis were recorded.

### *Videotaping and Reliability*

We videotaped the interviews to test interrater reliability of global improvement ratings. Twelve patients allowed their videotapes to be retained, and 11 of these tapes were of sufficiently good technical quality to permit review. Each videotape was reviewed blindly by an author in a different site; a state hospital tape was reviewed by a university hospital staff member, and vice versa. On the basis of global improvement at the end of the 10-minute infusion, each patient was categorized as either "responder" or "nonresponder" according to the previously stated criteria.

### *Statistics*

Patient age, weight, drug doses, and ratings are presented as means and standard deviations. The proportions of responders and nonresponders in the amobarbital and placebo conditions were compared by using Fisher's exact test. The magnitude of change in the arousal rating of the responders was tested with a two-tailed signed ranks test. The contributions of gender, medication status, and discharge diagnosis to response were assessed with Fisher's exact test. The contributions of age, weight, total dose of amobarbital, and weight-adjusted dose of amobarbital to response were assessed with two-tailed t tests for unpaired data. The reliability of our blinded videotaped ratings of responder status was tested with a phi correlation for dichotomous variables. The phi coefficient was then converted to a chi-square for significance testing.

## RESULTS

Six of the 10 patients randomly assigned to receive amobarbital were judged responders, whereas none of the 10 assigned to saline responded (p=0.005, Fisher's exact test). Of the four nonresponders to amobarbital, none responded to the follow-up interview with saline. By contrast, four of the initial nonresponders to saline became responders when blindly crossed to the amobarbital follow-up. Therefore, eventually 10 (50%) of the 20 patients responded to amobarbital, and none responded to saline.

Of the 11 patients whose videotapes were reviewed, six had been judged responders when given amobarbital interviews, and five were nonresponders. All 11 were identically classified by the raters of the videotapes (phi=1.00, $\chi^2$=12, df=1, p<0.001).

The baseline mean arousal rating for the 10 responders was 1.9 (SD=0.6). By the 4th minute of the amobarbital infusion, the score was 3.3 (SD=0.7), which was a significant improvement (p<0.02). Improvement in the arousal score continued through the 10th minute (mean=4.3, SD=0.8; p<0.002). The nonresponders showed no significant change in arousal ratings between baseline and the 10th minute (mean=2.3, SD=0.9, versus mean=2.1, SD=1.0).

There were no significant differences between responders and nonresponders in age, gender, affective versus nonaffective diagnosis, medication status in the previous 24 hours, weight, total dose of amobarbital, or mean dose of amobarbital in milligrams per kilogram of body weight. There was, however, significantly greater variance in the weight-adjusted amobarbital dose in nonresponders than responders (table 1).

After the amobarbital interview the choice of treatment was at the attending physician's discretion. A review of the discharge summaries produced the following final diagnoses: schizophrenia (N=6), unipolar depression (N=5), bipolar depression (N=4), mania (N=3), brief reactive psychosis (N=1), and dementia (N=1).

## DISCUSSION

To our knowledge, this study is the first to demonstrate the superiority of intravenous amobarbital over placebo in relieving a psychiatric symptom. Some clinicians now prefer to use benzodiazepines in relieving catatonic symptoms (11–13), but we felt that an investigation of amobarbital was indicated because it remains the historic "gold standard" and the basis of a rich clinical literature. Although this study focused on catatonic mutism, the literature suggests other catatonic symptoms would be equally responsive (14). Intravenous saline with our semistructured interview was completely ineffective in relieving catatonic mutism. This suggests that some change in the patient's physiology must occur to dispel catatonic mutism in the brief time of our interview. Even so, only 50% of our 20 patients responded to amobarbital. The responders showed signs of improvement by the 4th minute. The 100% concordance of our videotape-based reliability ratings of responders may seem surprisingly high, but "definite and sustained" improvement in our target symptom of mutism was easy to identify. Many of our nonresponders had partial or unsustained improvements in mutism, and by strictly defining our criteria for response we improved our reliability while losing some sensitivity to response.

Few identifiable differences separated responders from nonresponders. Although the responders had a higher mean age and higher prevalences of female sex and mood disorders, there were no significant differences in age, gender, diagnosis, weight, medication status, total dose of amobarbital, or weight-adjusted dose. Our small number of subjects may have limited our power to discern significant differences between responders and nonresponders. The variance in the weight-adjusted dose of amobarbital was significantly greater in the nonresponders. Some nonresponders fell asleep with as little as 100 mg of amobarbital, whereas others received 500 mg without effect. Although it is possible that greater flexibility in our dosing protocol might have resulted in a higher response rate, it is equally likely that patient factors accounted for the large variation in sensitivity in the nonresponders. Among the subjects studied by Elkes (5), the degree of response of catatonic patients to intravenous amobarbital was relatively fixed for each patient: "Higher doses did not lead to an increase in accessibility, but would merely result in sleep." Although we agree with Elkes that patient factors may limit the degree of patient responsiveness, we believe that the degree of responsiveness could change from one catatonic episode to another within the same patient. We have had the opportunity to administer multiple amobarbital interviews separated by months to patients with recurrent episodes of catatonia and have found that some patients respond during one interview but not the next.

Whether the response of catatonic mutism to intravenous amobarbital implicates a specific neurochemical pathophysiology is open to debate. Amobarbital, like other barbiturates, probably has a GABA-ergic agonist effect (15). Benzodiazepines and ECT also relieve catatonia and may exert their therapeutic effects through GABA-ergic pathways (16–18). On the other hand, we have seen catatonia relieved in 1 to 2 days with intramuscular neuroleptics or intramuscular amitriptyline. Also, studies published decades ago (19, 20) showed sudden relief of catatonia with inhalation of 30% carbon dioxide or subcoma doses of intramuscular insulin. We suggest that although a change in the patient's physiology is necessary to relieve catatonia, the type of physiologic change may be varied.

The risk-benefit ratio of performing an amobarbital interview is favorable. We have had no untoward events in our experience with amobarbital in catatonia. Benzodiazepines may be as effective and perhaps safer, but no controlled trials exist to our knowledge. In summary, intravenous amobarbital was superior to saline in relieving catatonic mutism during a brief interview. Nevertheless, only 50% of our patients responded. The amobarbital interview is useful, low risk, and inexpensive with the proper technique.

**APPENDIX 1. Statements/Questions in Semistructured Amobarbital Interview (given in any order, depending on interview flow)**

1. What is your name (age, or residence)?
2. Why are you here?
3. Do you know where you are?

4. Why are you not talking?
5. Are you uncomfortable?
6. We are giving you medicine in your vein that may let you tell us what is wrong.
7. We are going to take care of you here.
8. You may be feeling relaxed; that is a good sign.
9. This is a safe place to talk.
10. We want to help you and hear about your worries.

**APPENDIX 2. Scale for Rating Arousal and Reactivity During Amobarbital Interview**

1. No meaningful response to questioning or tactile stimulation; appears stuporous.
2. Interrupted or semipurposeful response to questioning or tactile stimuli; appears stuporous.
3. Makes meaningful response to questioning or tactile stimuli, but no spontaneous or voluntary communication.
4. Spontaneous or voluntary communication, but patient appears asleep or unmoving.
5. Spontaneous or voluntary communication, and the patient appears awake with spontaneous movements.

**APPENDIX 3. Scale for Rating Clinical Global Improvement at End of 10-Minute Amobarbital Interview**

Compared with baseline this patient is now . . .
1. Clinically worse.
2. Clinically unchanged.
3. Mildly or transiently improved.
4. Showing definite and sustained improvement.
5. Dramatically improved.

# The Role of Violence in Decisions About Hospitalization From the Psychiatric Emergency Room

Dale E. McNiel, Ph.D., Richard S. Myers, M.D., Harriet K. Zeiner, Ph.D.,
Harriet L. Wolfe, M.D., and Chris Hatcher, Ph.D.

*Objective: The authors evaluated the relationship between violent behavior and decision making about hospitalization from the psychiatric emergency room. Method: The medical charts of 321 patients evaluated in an urban psychiatric emergency room during a 4-week period were reviewed retrospectively. Violent behavior was defined as physical attacks on persons or fear-inducing behavior before or during the evaluation in the emergency room; and its value in predicting hospitalization decisions was assessed with logistic regression analyses that also included 12 demographic, clinical, and contextual variables. Results: A model predicting hospitalization decisions was developed and cross-validated. Although violent patients were more likely to be hospitalized than nonviolent patients, clinical variables such as diagnosis and overall severity of psychiatric impairment were more important than violent behavior in predicting hospitalization decisions. Conclusions: Despite legal pressures to focus on overt behaviors such as violence as a basis for liability prevention and civil commitment, clinicians in this study did not allocate inpatient resources to preventively detain persons unlikely to benefit from treatment. Rather, they hospitalized the most severely disturbed patients, with diagnoses such as schizophrenic and manic disorders for which a widely accepted therapeutic armamentarium exists. The results are consistent with clinical recommendations that in the evaluation of the violent patient, attention needs to be given to the underlying disorder, since violent behavior itself can result from diverse causes only some of which require inpatient psychiatric treatment.*

(Am J Psychiatry 1992; 149:207–212)

The urban psychiatric emergency service has become a major point of entry to inpatient treatment for the severely mentally ill (1, 2). A large subgroup of patients who come to psychiatric emergency services have been recently violent (3, 4). Although clinically oriented criteria for decision making about hospitalizing violent patients have been proposed (5), there is controversy about whether legal considerations have unduly influenced clinical decisions about hospitalizing violent patients. Some have suggested that legal developments, such as the widespread adoption of dangerousness as a standard for civil commitment and the creation of a legal duty to protect the potential victims of patients' violence, have resulted in the use of hospitalization for preventive detention of violent patients who are unlikely to benefit from treatment (6, 7). However, research about the relationship between violence and referral from the psychiatric emergency room for hospital admission is limited. That is, while violence has been correlated with the decision to hospitalize (8), previous studies typically have not evaluated the relationship between violence and hospitalization in the context of patients' other clinical characteristics, such as level and type of psychopathology. The present study will provide information about this topic by evaluating the relationship between violence and hospitalization decisions while taking into account other clinical characteristics which have also been associated with hospitalization decisions.

Previous research on the decision to hospitalize patients from the psychiatric emergency room has often yielded conflicting results. Several studies have identified demographic, clinical, and contextual variables that are associated with hospitalization decisions. Demographic predictors have included age (9), gender (10),

ethnicity (11), and employment status (12). Contextual variables such as family supports (13) and referral source (14) have also been correlated with hospitalization decisions. However, clinical variables such as diagnosis, symptoms, and indications of dangerousness to self and others have been more consistently associated with hospital admission (8, 15). Part of the reason for the conflicting results of previous studies may have been a failure to consider the intercorrelations between variables associated with hospitalization decisions and failure to cross-validate predictive models (15). The present study will improve on the design of most previous studies by using multivariate methods that take into account the intercorrelations between variables and will cross-validate models predicting hospitalization based on these variables. In this way the influence of violent behavior on hospitalization decisions is expected to be evaluated in a relatively reliable fashion.

This study addressed three specific questions: 1) What demographic, clinical, and contextual variables are associated with hospitalization decisions in a large, urban psychiatric emergency room? 2) What is the relationship between violent behavior, before or during the initial evaluation in the psychiatric emergency room, and referral for hospitalization? and 3) How useful is knowledge that a patient has been recently violent in predicting hospitalization decisions when other correlates of hospital referral are taken into account?

## METHOD

### *Procedure*

The study was conducted in the psychiatric emergency service of a university-affiliated hospital funded to serve the city and county of San Francisco. The sample included all patients evaluated in the psychiatric emergency service during a 4-week period in August 1988. If a patient had more than one visit to the psychiatric emergency service during the study period, only the first visit was included. The final sample consisted of 321 unduplicated patients.

The patients' charts were reviewed retrospectively to determine whether or not they were referred for inpatient psychiatric admission from the psychiatric emergency service, as well as for a number of demographic, contextual, and clinical variables that previous research has suggested are associated with hospitalization decisions. Demographic variables included gender, age, ethnic background, and employment status. Contextual variables included referral source and whether or not the patient lived with family. Clinical variables included primary psychiatric diagnosis, based on the *DSM-III-R;* overall severity of psychiatric impairment at the time of admission to the psychiatric emergency service, based on the treating clinician's rating on the Global Assessment Scale (GAS) (16), a widely used measure that has been shown to have good reliability and validity (16–17); a rating by the treating clinician of whether or not drug or alcohol problems were present; and the extent of recent suicidal behavior. Suicidal behavior was rated on the Longitudinal Inventory of Function and Encounters developed by Hargreaves, LeGoullon, and Gaynor in 1983. The rating of suicidal behavior on this scale ranges between none, threat, gesture, and attempt. The reliability and validity of the Longitudinal Inventory of Function and Encounters have been documented in previous research (18–20). The charts also were evaluated for the presence or absence of violent behavior during the two weeks before admission to the psychiatric emergency service, based on a modification, used in several previous studies (21–23), of a rating form developed by Lagos et al. (24), which includes three levels of increasingly severe violence: no violence, fear-inducing behavior (i.e., verbal attacks, threats to attack persons, and attacks on objects), and physical attacks on persons. If a chart indicated that more than one type of violence had occurred, only the most serious type was retained. We also evaluated the presence or absence of violent behavior during the first 24 hours that the patient was in the psychiatric emergency service. The ratings were made by experienced clinical staff who completed training in the coding system to a criterion interrater reliability (25) of kappa=0.75 before starting the chart reviews.

### *Data Analysis*

To describe the demographic, clinical, and contextual variables associated with hospitalization decisions, we first examined the relationship between each patient characteristic separately, using chi-square analyses, corrected for continuity when appropriate. A similar strategy was employed to describe the relationship of violent behavior to hospitalization decisions.

To assess how useful information about violent behavior was in predicting hospitalization decisions when other correlates of hospital referral are taken into account, we used logistic regression methodology. This approach combines information from several patient characteristics to yield a prediction of whether or not the patient will be hospitalized. Following the method described by Mosteller and Tukey (26), we included in each model variables that previous research has consistently found to predict hospitalization decisions (i.e., preadmission violence, suicidal behavior, primary diagnosis, and level of functioning as indicated by GAS score). Next, variables that have received some support in the literature as being important to hospitalization decisions (e.g., presence of concomitant drug and alcohol problems and presence of assaultive or fear-inducing behavior in the psychiatric emergency service) were added to the model, which was then subjected to a backward elimination procedure whereby variables that did not contribute significantly ($p<0.05$) to the classification of whether or not patients were hospitalized were removed from the model. Finally, variables that have received only inconsistent support in the literature as determinants of hospitalization (e.g., ethnicity, gender, living with family, referral source, and employment status) were subjected to a forward selection procedure, whereby they were added to the model if their inclusion resulted in a significant ($p<0.05$) increase in the ability of the model to predict hospitalization decisions.

To permit later cross-validation analyses, we first developed the prediction model on a subset of two-thirds of the patients that had been selected randomly with stratification on these variables: diagnosis, violent behavior, suicidal behavior, and GAS score. Then, we cross-validated the model by applying it to the remaining one-third of the patients and assessing how accurately the patients were classified as to hospitalization decisions.

## RESULTS

### *Characteristics Associated With Hospitalization*

Thirty-nine percent (N=124) of the 321 patients were referred for psychiatric hospitalization after evaluation in the psychiatric emergency service; 19% (N=60) were referred to outpatient treatment, day treatment, or community residential treatment such as halfway houses; 11% (N=36) were referred to drug or alcohol treatment programs; 12% (N=39) were referred for inpatient medical (nonpsychiatric) treatment; and 19% (N=62) had other dispositions, such as other social service or legal referrals and patient refused referral. As shown in table 1, patients were significantly more likely to be hospitalized if they were male and if they were unemployed. However, other demographic and contextual variables such as age, ethnic background, referral source, and residing with family did not have a statistically significant association with hospitalization decisions. Table 2 shows that patients' clinical characteristics were more closely associated with decisions about hospitalization. Patients with a primary diagnosis of schizophrenia were significantly more likely to be hospitalized, whereas patients with substance abuse disorders were less likely to be hospitalized. Similarly, patients with more severe overall psychiatric impairment, as indicated by lower ratings on the Global Assessment Scale, were more likely to be hospitalized. Interestingly, patients with a recent history of suicidal behavior were underrepresented in the group of patients referred for inpatient treatment. Although violent behavior in the psychiatric emergency service was not significantly associated with hospitalization, there was a marginally significant trend for preadmission violence to be associated with referral for hospitalization. Similarly, there was a trend for patients whose mental disorders were accompanied by drug and/or alcohol abuse to be less likely to be hospitalized than other patients.

### *Logistic Regression Analyses*

The first step in the logistic regression analysis was to compute a model including six variables that had been consistently shown in previous research to predict hospitalization: presence or absence of preadmission physical attacks and/or fear-inducing behavior, extent of suicidal behavior, primary diagnosis (schizophrenic or not, manic or not); and level of functioning as indicated by GAS score. To permit later cross-validation analyses, the model was derived on two-thirds of the sample (N=169), a subgroup that was randomly selected from the total sample after stratification by the variables to be included in the model. (The subsample of 169 patients is two-thirds of the 263 patients with complete data on all variables; 18% [N=58] of the 321 patients in the original sample had missing values on some variables and therefore could not be included in the regression analyses.) Two other variables, which have received some support in previous studies as predictors of hospitalization decisions (i.e., the presence of drug or alcohol problems in addition to mental disorders and the presence of physical attacks or fear-inducing behavior during the psychiatric emergency service visit) were then added to the model, which was subjected to a backward elimination procedure; neither of these additional variables

significantly ($p<0.05$) enhanced the predictive capacity of the model, so both were eliminated. Finally, several variables that some research has indicated are possibly useful in predicting hospitalization decisions (i.e., whether the subject resides with family, whether he or she is currently employed, referral source [police or other], age, gender, and interactions between manic or schizophrenic diagnosis and assaultive or fear-inducing behavior) were subjected to a forward selection procedure in which they were permitted to enter the model if this enhanced the predictive capacity of the model to a statistically significant degree ($p<0.05$). The only new variable to be retained after this step was gender.

Table 3 summarizes the final model resulting from the logistic regression analyses, which had an overall significance of $\chi^2$=45.48, df=7, $p<0.00001$. Clearly, violent and suicidal behaviors contributed little to the prediction of hospitalization decisions when diagnosis and overall severity of psychiatric impairment were taken into account. The clinical variables of diagnosis (schizophrenic or manic) and level of global impairment (GAS score) were the most important predictors of hospital admission. In addition to reporting the significance level of each variable in the model, table 3 gives odds ratios for each variable, i.e., the odds of hospitalization based on that variable when the other variables in the model are held constant. For dichotomous predictor variables (e.g., schizophrenic or not), the odds ratio represents the multiplicative change in the odds of hospitalization as the predictor changes from absence of a condition to presence of the condition; for continuous predictor variables (e.g., GAS score), the odds ratio represents the multiplicative change in the odds for each unit change in that predictor variable. The model correctly classified 73.4% of the patients, with a sensitivity of 78.3%, a specificity of 70.0%, a false-positive rate of 35.7%, and a false-negative rate of 17.6%.

To assess the stability of the prediction equation, we conducted a cross-validation analysis. We applied the previously mentioned model, which had been derived on two-thirds of the sample, to the remaining one-third of the sample. When the model was applied to the 94 subjects in the cross-validation subsample, 69.1% of the subjects were correctly classified, the sensitivity was 55.3%, the specificity was 78.6%, the false-negative rate was 27.9%, and the false-positive rate was 36.4%. Although some shrinkage in the sensitivity of the model would be expected on statistical grounds, the overall results of the cross-validation analysis suggest that the logistic regression models have a reasonable degree of stability in classifying which patients will and will not be hospitalized.

## DISCUSSION

These results suggest that clinical variables such as diagnosis and severity of psychiatric impairment are more important predictors of the decision to hospitalize patients from the psychiatric emergency room than are violent and suicidal behavior. In spite of legal pressures to focus on overt behaviors as a basis for liability prevention and civil commitment, clinicians in this study did not allocate inpatient resources to preventively detain persons unlikely to benefit from treatment. Rather, they hospitalized the most severely disturbed patients, with diagnoses such as schizophrenic and manic disorders for which a widely accepted therapeutic armamentarium exists. This finding is reassuring in that treatment objectives do not appear to have been neglected because of legal concerns about patient behavior. This result is also consistent with clinical recommendations that in the evaluation of the violent patient, attention needs to be given to the underlying disorder, since violent behavior itself can result from many diverse causes only some of which require inpatient treatment (5). Clearly, many patients who had displayed overt aggression before or after coming to the psychiatric emergency service were not felt to require inpatient psychiatric treatment and were instead referred to alternatives such as outpatient treatment, drug and alcohol programs, primary medical care, and the legal system.

Although our main research question was addressed by the multivariate analyses, examination of the individual patients' characteristics suggests similarities and differences between our sample and those of other studies on hospitalization decisions. As with other reports (9, 10), we found that diagnosis (e.g., of schizophrenia) and recent violence were associated with the decision to hospitalize. Our finding of an inverse relationship between recent suicidal behavior (e.g., threats and gestures) and hospitalization is unusual.

It is possible that an influence on these findings was the nature of our psychiatric emergency service, which has a holding area and staff on duty 24 hours per day. Gillig et al. (27) have reported that short-term holding areas in psychiatric emergency services can help avert hospitalization for many patients. Typical examples from our data set include patients with personality disorders or substance abuse disorders who came to the psychiatric emergency service during suicidal crises or who were intoxicated. In settings without access to a holding area, staff may have to hospitalize such patients.

**TABLE 3. Summary of Logistic Regression Analyses to Predict Odds of Hospitalization From the Psychiatric Emergency Room**

| Variable | Odds Ratio | Item $\chi^2$ | p |
|---|---|---|---|
| Schizophrenia diagnosis | 5.92 | 17.43 | <0.001 |
| GAS score | 0.94 | 8.95 | <0.003 |
| Manic episode diagnosis | 3.87 | 5.93 | <0.02 |
| Male gender | 2.28 | 4.40 | <0.04 |
| Suicidal behavior | 1.19 | 0.71 | n.s. |
| Preadmission physical attacks | 1.28 | 0.19 | n.s. |
| Preadmission fear-inducing behavior | 1.47 | 0.66 | n.s. |

This study focused on hospitalization decisions among a heterogeneous group of patients who were evaluated under a variety of legal and civil commitment circumstances. The results are consistent, however, with a study of emergency civil commitment by Segal et al. (28), who found that patients who were committed were more seriously ill and more dangerous.

Our finding that gender was associated with inpatient admission was puzzling, although some previous research has also reported this finding (10). Given reports that violence by psychiatric patients has a complex relationship with gender, depending on the setting (23), further study is needed to explain the association of patients' gender with clinical decision making about hospitalization.

We should point out that this report did not evaluate clinician variables such as the subjective explanation given by each clinician for his or her decisions. Although this is of interest, past research indicates that clinicians' explanations of their reasons typically are less predictive of the outcome for decisions than are empirical correlates of the decision (29) (such as those identified in this study). Future prospective studies are needed to assess how variables such as clinician training and the availability of specialized treatment resources (e.g., intensive case management, acute diversion units, and mobile crisis units) can affect the use of community-based treatment for patients whose clinical presentation includes violent behavior. The results of this study suggest a pattern of service delivery whereby the evaluation of individual patients considers the possibility of community-based treatment for patients depending on their mental disorder, even if the patients have displayed violent or suicidal behavior. Future research is needed to evaluate the impact of such decision-making patterns on patients' course and outcome.

---

*Objective: The purpose of this study was to examine patterns of co-occurrence of axis II disorders in a group of consecutive patients evaluated with two contrasting structured interviews. Method: One hundred of 106 consecutive applicants for long-term, inpatient treatment of severe personality psychopathology were assessed, face-to-face, by psychiatrists using the Structured Clinical Interview for DSM-III-R Personality Disorders (SCID-II) and the Personality Disorder Examination (PDE). The percent of co-occurrence of pairs of disorders diagnosed by each structured interview separately was calculated, and significance levels were determined by using chi-square tests of independence. Finally, odds ratios were computed for the odds of each pair of disorders occurring together compared with the odds for the occurrence of each disorder alone. Results: The two interview methods revealed different comorbidity patterns. Significant covariation was found for 29 pairs of disorders diagnosed with the PDE, compared with 12 pairs diagnosed with the SCID-II. Six pairs of disorders covaried significantly and were associated with odds ratios greater than 4: histrionic with borderline, histrionic with narcissistic, narcissistic with antisocial, narcissistic with passive-aggressive, avoidant with schizotypal, and avoidant with dependent. Conclusions: Substantial overlap occurred among personality disorders. In this group of patients, consistent patterns of comorbidity involving narcissistic, avoidant, and histrionic personality disorders suggest that categorical distinctions between them and certain other* DSM-III-R *personality disorders may be illusory. The question of which of two overlapping disorders is more valid, however, is left unanswered. For clinical purposes, a two-level diagnostic convention is proposed.*

(Am J Psychiatry 1992; 149:213–220)

---

Comorbidity is an important but elusive concept in psychopathology. Diagnostic heterogeneity may contribute substantially to differences in research findings, leading to confusing, inconclusive, or contradictory results. Clinically, heterogeneity may contribute to differential treatment responses among superficially similar patients.

The capacity to differentiate syndromal complexity from multiple, discrete, coexisting disorders in a given patient may make a critical difference in a recommended treatment approach or a research design (1). For example, is *DSM-III-R* panic disorder with agoraphobia one disorder or two? If one, how is it that a syndrome of agoraphobia without a history of panic disorder (or even without limited symptom attacks) occurs? If two, how does the co-occurrence of these two presumably independent clinical states differ from the occurrence of intense anxiety that is considered an integral aspect of the syndrome of simple phobia? Is generalized social phobia a more severe form of the more limited type or is it a discrete disorder? With respect to axis II, it is unclear whether the 11 specific *DSM-III-R* diagnoses are different disorders, as demonstrated by the usual standards of diagnostic validity (e.g., discrete family histories or differential treatment responses) or if some, at least, are manifestations of more fundamental psychopathological disturbances (differing in severity, duration, stage of illness, aspect of functioning affected, or other nondiscrete variable).

The term "comorbidity" is generally used to mean coexisting disorders that have distinct etiologies, such as pneumonia and pneumothorax, or schizophrenia and toxic delirium. On axis II, disorders overlap extensively (2, 3), and most studies that have used semistructured interviews to systematically evaluate patients for all axis II disorders (3, 4) have found that at least 50% of patients have two or more coexisting personality dis-

orders. It may be, then, that a dimensional approach is better suited for axis II disorders (5) than a categorical one that results in an unwieldy list of presumably comorbid diagnoses to describe "character pathology" in a given patient.

For example, borderline personality disorder has been shown to be transmitted in families (6), but it has also been shown to overlap extensively with other axis II disorders (7). Familial transmission has also been suggested for schizotypal (8), paranoid (9), and antisocial (10) personality disorders; the rest have not been studied from a family perspective. It is not clear if these disorders are transmitted independently of each other in families or if, instead, certain groups of axis II disorders coexist in patients and their families with regularity. To our knowledge, only one twin or adoption study of borderline personality disorder has been done to more specifically address its heritability (11). Biological markers have been proposed but not identified as specific for the disorder (12), and it has been suggested that borderline personality disorder may consist of several different disorders, including a subgroup representing an atypical affective disorder (13). Some researchers have posited that borderline personality disorder itself is a dimensional construct rather than a categorical one (7, 14, 15).

Widiger and Rogers (16) have argued that the three clusters of disorders on axis II (odd/eccentric, dramatic/emotional, and anxious/fearful) may be the more fundamental underlying conditions. Factor analytic studies have validated the cluster concept (17). On the basis of this model, the dramatic/emotional cluster could be a single personality disorder with different manifestations in behavior, similar to the notion of depression as a type of mood disorder with particular manifestations. Kernberg (18) has described a theoretical concept along these lines for borderline conditions, which he calls "borderline personality organization." His concept is of a general disturbance that includes not only the *DSM-III-R* category of borderline personality disorder but many of the other axis II disorders as well (19). Alternatively, such an underlying disorder could be an axis I disorder itself, such as depression, which, when chronic, leads to alterations in personality.

Most previously published studies on comorbidity among axis II disorders used either diagnoses made by clinical judgment rather than by research interviews (2, 7, 20) or *DSM-III* rather than *DSM-III-R* criteria (3, 20, 21). Until the emergence of semistructured, clinical research interviews, no systematic data were available to clarify the adequacy of a categorical approach to the diagnosis of personality psychopathology.

In the present report, we examine patterns of co-occurrence of axis II disorders in a group of 100 patients evaluated with two contrasting structured interviews, the Structured Clinical Interview for DSM-III-R Personality Disorders (SCID-II) (22) and the Personality Disorder Examination (PDE) (23). Differences in prevalence rates for any given disorder and presumed relationships between disorders may be due to differences in assessment methods (15, 24), sample selection (7), or changes in diagnostic criteria such as those which occurred for some axis II disorders when *DSM-III-R* replaced *DSM-III* (2). By using two different interviews based on *DSM-III-R* in the same patient group, our aim was to identify the similarities and differences between the interviews in results regarding diagnostic overlap. Consistent patterns of comorbidity, indicated by agreement between the two interviews that specific disorders were related, would suggest that categorical distinctions between certain *DSM-III-R* personality disorders may be illusory.

## METHOD

### *Subjects and Interviews*

One hundred of 106 consecutive applicants for long-term, inpatient treatment of severe personality psychopathology on our clinical research service were assessed, face-to-face, by psychiatrists using two semistructured interviews for diagnosing axis II personality disorders. Seventy-one percent of the subjects were women, 85% were white, 93% were at least high school graduates (38% were college graduates), 81% had never been married, and 66% had been employed during the year before the evaluation. The mean age of the subjects was 27.7 years (SD=6.2).

The two interviews, the SCID-II (22) and the PDE (23), were selected because they differ from each other in approach to the diagnosis of personality disorders and in scoring method, but each gives diagnoses based on *DSM-III-R* criteria. Each interview has been subjected to formal studies of reliability, and their reliabilities have been found to be comparable (25, 26).

*DSM-III-R* was in development during this study, and the criteria for personality disorders were being revised. At the time we initiated this study, both structured interviews contained the diagnostic criteria from the Oct. 5, 1985, draft of *DSM-III-R*. Before the data collection was complete, the criteria had undergone two revisions, in Aug. 1, 1986, and in the final draft manual, published on June 1, 1987. We revised our instruments once during the course of the study to correspond to the final axis II criteria. A comparison of the criteria in the Oct. 5, 1985, draft with the final manual's criteria reveals identical criteria content (but not necessarily wording) for schizotypal, histrionic, antisocial, obsessive-compulsive, and passive-aggressive personality disorders. Paranoid, narcissistic, borderline, and dependent personality disorders shared all but one criterion each in the two versions. Schizoid and avoidant personality disorders had two fewer criteria in the final *DSM-III-R* than in the preliminary draft. The category of personality disorders not otherwise specified was not used.

### *Assessment Procedure and Interviewers*

Eighty-eight of the 100 patients received both structured interviews on the same day. Of the remaining 12

**TABLE 1. Prevalence of Personality Disorders in 100 Patients Diagnosed With the Structured Clinical Interview for DSM-III-R Personality Disorders (SCID-II) and the Personality Disorder Examination (PDE)**

| | Prevalence (%) | | Difference in Rates[b] | |
|---|---|---|---|---|
| Personality Disorder[a] | SCID-II | PDE | $\chi^2$ | p |
| Paranoid | 35 | 15 | 14.29 | <0.002 |
| Schizoid | 12 | 1 | 11.00 | <0.002 |
| Schizotypal | 18 | 19 | 0.06 | n.s. |
| Antisocial | 7 | 9 | 0.67 | n.s. |
| Borderline | 62 | 64 | 0.18 | n.s. |
| Histrionic | 25 | 17 | 4.57 | <0.10 |
| Narcissistic | 17 | 20 | 0.53 | n.s. |
| Avoidant | 50 | 40 | 4.55 | <0.10 |

| 11 | 0 | 0 |

patients, three were reinterviewed within 1 week, six within 1 month, and three within 2 months. (Six patients in the original group of 106 consecutive patients who never received the second interview were excluded from the study.) The interviews and interviewers were alternated in order, resulting in a balanced design. Each interview was conducted blind to the result of the other.

Ninety percent of the diagnostic interviews were administered by three of us (A.E.S., H.D.K., and S.E.H.). All interviewers were trained directly by developers of the structured interviews.

### *Analyses*

The percent of co-occurrence of pairs of disorders diagnosed by each structured interview separately were calculated. The percent of co-occurrence was defined as the number of patients who had both of any pair of disorders divided by the number of patients who had either (15). Significance levels were determined by using chi-square tests of independence with Yates's correction for continuity on 2×2 contingency tables. Finally, odds ratios were computed for the odds of each pair of disorders occurring together compared with the odds for the occurrence of each disorder alone. In general, odds ratios greater than 2 were considered noteworthy, and doubling of the ratio (i.e., odds ratios of 4, 8, 16, etc.) was considered an increase in the order of magnitude of the association.

## RESULTS

Overall, in this study group of chronically and severely disabled patients, personality disorders were prevalent (table 1). The 100 patients were assigned 290 personality disorder diagnoses by the SCID-II and 249 by the PDE. The most prevalent axis II diagnosis on which the two interviews showed a general consensus was borderline personality disorder, followed by avoidant and dependent personality disorders. The SCID-II diagnosed more cases than the PDE of six disorders; two of these differences were statistically significant (paranoid and schizoid personality disorders), and two were different enough to indicate a trend (histrionic and avoidant). Agreement on specific diagnoses generated by the two interviews ranged from good for dependent (kappa=0.66), antisocial (kappa=0.59), and histrionic (kappa=0.58) personality disorders to poor for schizoid (kappa=0.14), passive-aggressive (kappa=0.21), and paranoid (kappa=0.29) personality disorders. Overall, agreement between the interviews was modest.

Although the absolute number of patients assigned diagnoses of axis II disorders was greater for the SCID-II than for the PDE (86 versus 74) ($\chi^2$=12.00, df=1, p<0.002, McNemar's test, two-tailed), the number of disorders per patient among patients who had any axis II disorders was the same—3.4 for each of the two methods. As shown in table 2, regardless of method, patients more often had more than one personality disorder than a single disorder. In no case did the PDE indicate that a patient had at least one personality disorder when the SCID-II did not as well.

Table 3 shows the percent of co-occurrence of the personality disorders diagnosed with the two methods. Significant covariation was found for 29 pairs of disorders diagnosed with the PDE, compared with only 12 pairs of disorders diagnosed with the SCID-II, even though the PDE yielded fewer total diagnoses of personality disorders than did the SCID-II (249 versus 290). Only one pair of disorders (schizoid with schizotypal) significantly co-occurred according to SCID-II assessments that did not also co-occur according to the PDE (the PDE diagnosed only one patient as schizoid in the entire group of 100), but 18 pairs were significant by the PDE but not by the SCID-II. Eleven pairs of disorders significantly co-occurred by both methods; they were paranoid with schizotypal, paranoid with borderline, paranoid with avoidant, schizotypal with avoid-

[a] Co-occurrence was calculated from 2×2 tables and defined as the number of patients with both disorders divided by the number with either. Significance levels were determined by chi-square tests of independence with Yates's correction for continuity on 2×2 contingency tables.
[b] $p<0.05$.
[c] $p<0.01$.
[d] $p<0.001$.

ant, antisocial with narcissistic, borderline with histrionic, borderline with dependent, histrionic with narcissistic, passive-aggressive with narcissistic, avoidant with dependent, and obsessive-compulsive with dependent. The most significant covariations observed by both methods were for avoidant with schizotypal personality disorder and avoidant with dependent personality disorder.

Table 4 presents the odds ratios for the pairs of disorders as diagnosed by both interviews. Odds ratios are less sensitive than co-occurrence percentages to differences in marginal probabilities and, thus, to disparate base rates or prevalences. Odds ratios may be the preferred measure of comorbidity because they allow comparisons to be made across different study groups (27). Diagnoses made by the PDE were associated with many more notable odds ratios than diagnoses by the SCID-II; e.g., use of the PDE resulted in at least twice as many odds ratios greater than 4 and 8 and the only odds ratios greater than 16 and 32. With the effect of prevalence reduced, seven pairs of disorders were associated with high (greater than 4) odds ratios by both methods: histrionic with antisocial, histrionic with borderline, histrionic with narcissistic, narcissistic with antisocial, narcissistic with passive-aggressive, avoidant with schizotypal, and avoidant with dependent.

## DISCUSSION

By employing two axis II interviews and examining their consensus, we have attempted to identify consistent patterns of comorbidity among personality disorders. Were there axis II disorders that invariably co-occurred with either method?

The SCID-II diagnosed a greater number of disorders overall than did the PDE, but the SCID-II demonstrated considerably fewer patterns of significant co-occurrence. As we have discussed elsewhere (28), the formats of the SCID-II and the PDE are markedly different, and the possibility of a "halo effect" is more likely to occur with the SCID-II. A halo effect might be expected to

**TABLE 4. Odds Ratios for Co-Occurrence of Axis II Disorders in 100 Patients Diagnosed With the Structured Clinical Interview for DSM-III-R Personality Disorders (SCID-II) and the Personality Disorder Examination (PDE)**

| | Odds Ratio for Each Personality Disorder | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Personality Disorder | Paranoid | Schizoid | Schizotypal | Antisocial | Borderline | Histrionic | Narcissistic | Avoidant | Dependent | Obsessive-Compulsive | Passive-Aggressive |

| PDE (N=8) | | | | | | | | | | | |

lead to more frequent diagnoses in some categories because the interviewer can probe for confirmation of an emerging positive diagnosis as a particular category is being surveyed. On the other hand, the halo effect may also lead to less frequent diagnoses if they are prematurely dismissed after a different positive diagnosis seems likely. In addition, as discussed elsewhere (28), the algorithms for the PDE that establish thresholds for the presence or absence of criteria are more stringent than the guidelines of the SCID-II, and, as a result, fewer diagnoses in most categories are made.

Higher base rates of disorders are generally associated with higher rates of co-occurrence, but high co-occurrence rates or the percent of co-occurrence may not reflect comorbidity. Widiger et al. (15) evaluated available studies of personality disorders that included sufficient data to analyze co-occurrence percentages for all *DSM-III* axis II disorders (2, 3, 20, 21). They pointed out that percentages may be misleading if considered incorrectly. For example, when evaluating all patients who have one or the other or both of a pair of personality disorders, half of the patients with each disorder will also have the other disorder when the co-occurrence rate is only 33%.

Eleven pairs of disorders diagnosed with both the PDE and the SCID-II significantly ($p<0.05$ or greater) covaried. When both interviews demonstrate significant patterns of co-occurrence, the likelihood that these patterns are meaningful and nonrandom is greater. Comorbidity analysis, however, should take into account widely disparate base rates. We used odds ratios to reduce the effect of difference in base rates. Six of the seven pairs of disorders with odds ratios of 4 or greater by both the PDE and SCID-II were also significant ($p<0.05$ or greater) according to co-occurrence percentages. The one exception was the co-occurrence of antisocial with histrionic personality disorder, which was significant by the PDE ($p<0.001$) but not by the SCID-II.

In this group of patients, therefore, the most significant comorbidity, as measured by two interviews and analyzed by two methods, occurred in six pairs of disorders. Three of these involved narcissistic personality disorder (with antisocial, histrionic, and passive-aggressive personality disorders). Two involved avoidant personality disorder (with schizotypal and dependent personality disorders). The sixth pair was borderline with histrionic personality disorder.

The analysis of Widiger et al. (15) also led them to conclude that comorbidity appears to be the norm in personality disorders. In their review, the diagnosis most frequently co-occurring with other axis II diagnoses was borderline personality disorder. However, three of the four studies they reviewed (3, 20, 21) were based on *DSM-III* data, and in the fourth study, Morey (2) pointed out that the revisions made by *DSM-III-R* substantially increased the degree of diagnostic overlap between the different axis II disorders. Although the prevalence of borderline personality disorder diagnoses remained about the same, the prevalence of some personality disorder diagnoses increased markedly with *DSM-III-R* criteria: e.g., 240% for avoidant, 300% for paranoid, 350% for narcissistic, and 800% for schizoid personality disorder. The two pairs of *DSM-III-R* disorders in Morey's study that had the highest percent of overlap were schizotypal with avoidant and schizotypal with paranoid personality disorder. Our results replicate the former relationship but not the latter.

A number of investigators (3, 20, 21, 29) have found high rates of co-occurrence of borderline and histrionic personality disorders defined by *DSM-III* criteria. In drafting *DSM-III-R,* specific efforts were made to reduce the degree of overlap between these disorders, yet in our data there remains significant co-occurrence of borderline and histrionic personality disorders defined by *DSM-III-R* criteria. We did not find significant overlap between borderline and narcissistic disorders, in contrast to the results of Pfohl et al. (3). We found only a questionable (by the PDE only) relationship of borderline personality disorder to schizotypal personality disorder. This is surprising, given the degree to which comorbidity research on borderline personality disorder has focused on this association (30, 31).

Trull et al. (32) studied *DSM-III* avoidant, schizoid, and dependent personality disorders and found that 71% of their avoidant patients were also dependent and that 50% of the dependent patients were also avoidant; these data are compatible with our findings. Avoidant personality disorder has been shown by others to overlap significantly with schizotypal personality disorder (3, 33), which is consistent with our data, and with paranoid personality disorder (21), which corresponds to our results based on co-occurrence percentages but not when adjusted for base rates by using odds ratios. Trull et al. did not find co-occurrence of schizoid and either dependent or avoidant personality disorders—also compatible with our data.

## RESEARCH AND CLINICAL IMPLICATIONS

As already mentioned, controversy persists regarding whether patterns of comorbidity on axis II represent independent disorders co-occurring in the same patients or, as Widiger and Frances (5) have argued, indicate that a dimensional system is more appropriate than the categorical system currently applied. Overlap in the content of diagnostic criteria for different disorders continues in *DSM-III-R,* and some of the disorders that co-occurred significantly with both diagnostic methods in this study have content overlap in their criteria. For example, narcissistic personality disorder co-occurred with histrionic, passive-aggressive, and antisocial personality disorders. Not only are these associations clinically intuitive, but selected criteria are either identical or similar for these disorders. A similar point can be made about the other three pairings that were significant with both interview methods by both co-occurrence rates and odds ratios, namely, schizotypal with avoidant, dependent with avoidant, and histrionic with borderline personality disorder. As an illustration of this overlap, "constantly seeks or demands reassurance or praise" is a criterion for histrionic personality disorder and "requires constant attention and admiration" is a criterion for narcissistic personality disorder. Similarly, "has no close friends or confidants" is a criterion for both schizotypal and avoidant personality disorders.

Certain co-occurrences in the PDE data seem clinically counterintuitive. For example, narcissistic and dependent or borderline and obsessive-compulsive personality disorders do not seem likely partners. Although theoretical constructs could be suggested (e.g., that a fear of dependency or engulfment produces the grandiose pseudo-independence of narcissism or that the chaotic impulsiveness of borderline personality disorder is defensively counteracted by attempts at rigid orderliness), it seems unlikely that questions based on *DSM-III-R* criteria, themselves aimed at measurable or observable behavior, would elicit such responses, even if they were present. It may be that the format of the 1985 PDE makes it more difficult for the clinician to weigh the meaning and importance of answers to individual questions because they are not keyed to specific disorders in the body of the interview itself. Thus, the clinician would not have the advantage of probing or challenging inconsistent or contradictory responses as he or she would with the SCID-II. This problem has been corrected to some extent in the 1988 version of the PDE (25).

Although the SCID-II pattern of comorbidity may seem to have more face validity, the halo effect mentioned earlier may have led to discovery of the expected. Interviewers may have operated on their clinical intuitions concerning which disorders they believed to be associated and which not and consciously or unconsciously may have altered their diagnostic thresholds accordingly. Widiger and Frances (34) have argued that an interview with a format similar to that of the PDE, which discourages diagnostic biases, is preferable in research on overlap between diagnostic criteria sets. Our use in this study of both interviews and our focus on congruent results would appear to balance the positive and negative aspects of either interview used alone.

In this group of patients with long-term and extensive psychopathology, certain apparent disorders might be derivatives or secondary by-products of pervasive axis I illness rather than coexisting independent conditions. Many of these patients, although referred for treatment of axis II pathology, had concomitant mood and anxiety disorders on axis I (our data in preparation). These axis I disorders may show consistent patterns of covariation with certain axis II disorders. Avoidant personality disorder, for example, could then be an "epiphenomenon," reflecting generally high anxiety levels or a behavioral pattern secondary to many years of illness.

Narcissistic personality disorder has been a controversial addition to the diagnostic nomenclature (35). We found here that it covaried with antisocial, histrionic, and passive-aggressive personality disorders, possibly implying certain underlying common features such as self-interest or insensitivity to others. From a clinical perspective, the disorders represent different psychopathological constructs, but whether narcissistic personality disorder is valid as a disorder in its own right or is a feature of other disorders is not clear.

Demonstration of significant and conceptually coherent overlap between diagnoses leaves unanswered the question of which of two overlapping disorders is the more valid. As yet, there is no clear-cut way to resolve this issue with respect to the personality disorders. Arguments may be made on the basis of theoretical models or historical tradition that one of the two overlapping disorders should be considered predominant and subsume the other, but counterarguments are also possible. The real question is whether each of the two diagnosed disorders contributes independently to some important clinical variable. Research designed to determine the unique contribution of individual personality disorder diagnoses to variation in external validators of personality psychopathology is sorely needed.

Our data suggest that there may be merit in maintaining the categorical diagnostic system to allow further research to be done. The two interviews used in this study did not produce identical prevalence rates or patterns of significant co-occurrence. Some specific disorders, such as antisocial personality disorder, may be readily assessed cross-sectionally; others may need longitudinal clinical observation for accurate assessment (36). Given the rates of multiple diagnoses and percents of co-occurrence found, however, we believe that a persuasive case can be made for a two-level diagnostic system on axis II for clinical use. For patients who meet criteria for two or fewer disorders (focal personality disorder), the current categorical system might be retained. For patients with more than two disorders, a single diagnosis of "extensive personality disorder" might be made, with a dimensional description of the predominant characteristics of the disorder. For example, a patient meeting criteria for three axis II disorders might be diagnosed as having "extensive personality disorder with paranoid, borderline, and narcissistic features." Such a method would allow continuity with research methodology incorporating the current axis II approach but would create a diagnostic convention that corresponds better with clinical practice. This hierarchy would require empirical testing and comparison with previously proposed hierarchies for personality disorders based on severity, such as those of Kernberg (18) and Millon (37).

A limitation of this study is its focus on severely ill patients whose personality psychopathology resulted in more than one personality disorder diagnosed with structured assessment methods. The findings may not generalize to outpatients who are less ill. We have recently completed a replication in a more highly functioning group of outpatients applying for psychoanalysis and are in the process of analyzing these data.

Future efforts should also attempt to further reduce overlap among the personality disorders by eliminating duplicate criteria and by identifying or developing criteria that can discriminate one diagnosis from another. Finally, it may eventually prove fruitful to collapse current categories into supraordinate groupings on the basis of factor analysis, multidimensional scaling, or other statistically based hierarchies.

# Self-Mutilation in Personality Disorders: Psychological and Biological Correlates

Daphne Simeon, M.D., Barbara Stanley, Ph.D., Allen Frances, M.D.,
J. John Mann, M.D., Ronald Winchel, M.D., and Michael Stanley, Ph.D.

*Objective: The goal of this study was to determine whether self-mutilators with personality disorders differ from nonmutilators with personality disorders in impulsivity, aggression, and other psychopathology and whether serotonergic dysfunction contributes to self-mutilation. Method: Twenty-six self-mutilators with personality disorders were matched to 26 control subjects with personality disorders for gender, age, education, axis I diagnosis of affective disorder, and axis II diagnosis of personality disorder. Numerous indexes of psychopathology as well as CSF 5-hydroxyindoleacetic acid (5-HIAA) levels and platelet imipramine binding sites ($B_{max}$) and affinity ($K_d$) were determined. Results: Self-mutilators had significantly more severe character pathology, had greater lifetime aggression, and were more antisocial than the control subjects. The self-mutilators scored higher on the Hamilton Rating Scale for Depression but not on the Beck Depression Inventory or the Beck Hopelessness Scale. The two groups did not differ on the Buss-Durkee Hostility and Guilt Inventory or on the Sensation Seeking Scale. The degree of self-mutilation was significantly correlated with impulsivity, chronic anger, and somatic anxiety. Both self-mutilation and impulsivity showed significant negative correlations with $B_{max}$, although the two groups did not differ in CSF 5-HIAA levels or in platelet imipramine binding. Conclusions: The results demonstrate the contribution of severe character pathology, aggression, impulsivity, anxiety, and anger to self-mutilation and provide preliminary support for the hypothesis of underlying serotonergic dysfunction facilitating self-mutilation.*

(Am J Psychiatry 1992; 149:221–226)

Self-mutilation is defined as deliberate harm to one's own body resulting in tissue damage, without a conscious intent to die. It is encountered predominantly in three groups of patients: in those with mental retardation and other organic conditions (stereotypic self-mutilation such as head banging), in those with psychoses (major self-mutilation such as self-enucleation and autocastration), and in those with personality disorders—commonly borderline personality disorder and, in incarcerated men, antisocial personality disorder (minor self-mutilation such as cutting or burning the skin) (1).

The phenomenon of self-mutilation has received relatively little attention in the psychiatric literature. The clinical literature on self-mutilation in patients with personality disorders consists mostly of descriptive, uncontrolled, and retrospective studies that present a bewildering and complex array of etiologies and psychopathological correlates without sufficient systematic observation and comparison. Typically, the behavior begins in adolescence and may persist for decades and result in great personal and social morbidity. The term "deliberate self-harm" has been proposed to delineate this behavior as a distinct syndrome of low lethality and repetitive, direct self-destructive behavior (2).

Relief of mounting tension and depersonalization is the single most common clinically identified correlate to self-mutilation; other cited psychological motivations include venting of anger, establishing control, forming an identity, influencing others, responding to self-hatred or guilt, discharging sexual feelings, and seeking euphoria. Underlying psychodynamic hypotheses are equally varied and include partial suicide as an attempt at self-healing, rage toward the self or the internalized bad object, symbolic castration, formation of ego boundaries, autoerotic gratification, mastery of menstruation, and procurement of a transitional object (1).

Social and cultural perspectives may also enrich our understanding of self-mutilating behavior (3); review of these perspectives is beyond the scope of this paper.

There are very few systematic studies, most of which involved a small number of subjects, and even fewer controlled studies investigating self-mutilation in personality disorders. Rosenthal et al. (4) compared female inpatients who had histories of wrist-cutting with female inpatients who had histories of suicide attempts by methods other than wrist-cutting. The women who cut themselves were more likely to have histories of early trauma and surgery, difficulties with menses, sexual identity confusion, chronic feelings of emptiness, and histories of eating disorders; the comparisons were not tested statistically and the diagnoses of the patients in the two groups were not specified. Schaffer et al. (5) compared self-mutilators with demographically matched subjects who had psychiatric disorders and found that the self-mutilators were much more likely to have borderline personality disorder. McKerracher et al. (6) and Gardner and Gardner (7) compared self-mutilators with nonmutilators who did not differ in their diagnoses of personality disorders and found that self-mutilators were significantly more obsessional. Bennum (8) compared self-mutilators with nonmutilating depressed patients and found that the two groups did not differ in depression or inwardly directed hostility but that the self-mutilators had greater outwardly directed hostility. Roy (9) compared self-mutilators, most of whom were diagnosed as having personality disorders, with control subjects, most of whom were diagnosed as having depressive neurosis, and found greater introversion, neuroticism, and hostility in the self-mutilators. These controlled studies provide a useful beginning to the systematic study of the psychology of self-mutilation, but the conclusions we can draw on the basis of their findings are limited by the heterogeneity of the groups compared and the diversity of the psychological variables investigated and the assessment instruments used.

Biological studies of self-mutilation in patients with personality disorders have been very limited. Coid et al. (10) conducted one study of the opiatergic system in habitual self-mutilators and found them to have higher plasma metenkephalin than control subjects. The potential role of the serotonergic system in self-mutilation is of great theoretical interest. Serotonergic dysfunction has been widely implicated in suicide, an act of aggression toward oneself, across diagnostic groups (11), as well as in acts of impulsiveness and aggression toward others. There have been several studies of the serotonergic system specifically in personality disorders, focusing on aggressive and impulsive behaviors. These studies have shown a relationship between low CSF 5-hydroxyindoleacetic acid (5-HIAA) levels and suicide attempts (12), history of aggressive behavior (12), impulsive nonviolence such as arson (13), and impulsive violent offenses (14). Similarly, Coccaro et al. (15) showed a correlation between blunted prolactin response to the 5-hydroxytryptamine (5-HT) agonist fenfluramine, indicating reduced central net serotonin transmission, and a history of suicide attempts, aggression, assault, irritability, and motor impulsiveness in subjects with personality disorders. Stoff et al. (16) and Birmaher et al. (17) studied children with conduct disorders and found a significant negative correlation between impulsive and aggressive behaviors and platelet imipramine binding, a peripheral marker thought to represent central presynaptic serotonin release.

In one study of serotonergic function in personality disorders that examined self-mutilation, Gardner et al. (18) compared 17 women who had borderline personality disorder with 17 normal control subjects and found no difference in CSF 5-HIAA levels between the two groups, as well as no difference in CSF 5-HIAA levels between the 12 self-mutilators and the five nonmutilators in the borderline group. The different rates of suicide attempters in these two subgroups (58% and 100%, respectively), however, may have confounded the results. The aggression and impulsivity characteristics of self-mutilation suggest the possibility that this behavior may indeed be mediated in part by an underlying serotonergic dysfunction. The potential role of other neurotransmitter systems such as the opiatergic and the dopaminergic (19) are beyond the scope of this investigation. This is the first study aimed at determining whether self-mutilators with personality disorders differ from nonmutilators with personality disorders in measures of serotonergic function and whether these measures correlate with self-mutilating behavior, aggression, impulsivity, and other associated psychopathology.

## METHOD

Twenty-six self-mutilators with personality disorders and 26 control subjects with personality disorders were drawn from a larger pool of 202 suicide attempters and diagnostic control subjects studied by Stanley et al. (work in progress). Out of a total of 43 self-mutilators in the larger study group, 11 were excluded because they had an axis I diagnosis of psychotic disorder and six were excluded because they had an axis I diagnosis of affective disorder without an axis II disorder. The remaining 26 self-mutilators had axis II diagnoses and are the subjects of this study. All patients and control subjects consented to participation in the study after its nature had been explained to them.

Self-mutilation was defined as deliberate injury to one's own body tissue without conscious intent to die. Self-mutilation was assessed by clinical interview with the Schedule for Interviewing Borderlines (20), which rates the degree of self-mutilation on a frequency scale of 1 to 4 on which 1=none, 2=mild (1–3 times per year), 3=moderate (4–11 times per year), and 4=severe (more than 12 times per year). The mean self-mutilation score in the self-mutilator group was 2.7 (SD=0.8). Half (N=13) of the 26 patients had a self-mutilation score of 2, 35% (N=9) had a score of 3, and 15% (N=4) had a score of 4. The 26 self-mutilators with personality disorders were matched to 26 control subjects out of the pool of 159 nonmutilators to maximize similarity in gender (20 women and six men), age, education, axis I diagnosis of affective disorder, and axis II diagnosis of personality disorder (table 1). The mean age of the self-mutilators was 31.0 years (SD=9.6); that of the nonmutilators was 31.4 (SD=9.4) (t<1, df=50, n.s.).

*DSM-III-R* diagnoses were determined by clinical interviews in combination with the Schedule for Affective Disorders and Schizophrenia (21) and the Schedule for Interviewing Borderlines (20). The two groups did not differ in their suicide attempt histories (table 1). Suicide attempts were defined as acts committed with a conscious intent to end one's life and requiring medical attention; by definition, suicide attempts and acts of self-mutilation are mutually exclusive.

Patients were hospitalized throughout the study. All patients underwent a medical examination and standard laboratory tests to ensure their ability to participate. Inclusion criteria were age 18 to 85 years. Exclusion criteria were physical conditions precluding a lumbar puncture, neurological disorders, history of head trauma, brain damage, mental retardation or other substantial cognitive impairment, and a current diagnosis of substance use, which could potentially confound neurochemical assessments. Patients who were receiving medication affecting the CNS entered a medication-free phase for 14 days or longer, after which the lumbar puncture was performed. Venipuncture immediately followed the lumbar puncture, and full clinical evaluations were completed within 72 hours.

Several measures designed to assess specific areas of psychopathology were administered. To assess depression, three scales were used: 1) the Hamilton Rating Scale for Depression, 2) the Beck Depression Inventory, and 3) the Beck Hopelessness Scale (22). To assess personality, five scales were used: 1) the Schedule for Interviewing Borderlines, Part II: Schedule for Borderline Personalities (20), a semistructured interview with 11 subscales that assess a broad range of borderline traits, 2) a semistructured interview of each patient's lifetime history of aggression that provides quantifiable information on multiple aspects of aggressive behavior such as tantrums, fights, arguments, assaults and illegal acts, 3) the MMPI psychopathic deviance subscale, a self-rating that assesses antisocial traits, 4) the Buss-Durkee Hostility and Guilt Inventory (23), a self-rating of seven subscales of hostility (assault, irritability, resentment, indirect hostility, negativism, suspiciousness, and verbal hostility) as well as guilt, and 5) the Sensation Seeking Scale (24), self-rated on four subscales (thrill and adventure seeking, experience seeking, disinhibition, and boredom susceptibility).

Biological measures included 1) CSF 5-HIAA levels, determined by high performance liquid chromatography using electrochemical detection, according to a method described elsewhere (25), and 2) number of platelet imipramine binding receptor sites ($B_{max}$) and affinity constant ($K_d$), determined by a method described elsewhere (26).

**TABLE 1. Characteristics of Subjects With Personality Disorders Who Were or Were Not Self-Mutilators**

| | Self-Mutilators (N=26) | | Nonmutilators (N=26) | | Comparison | | |
|---|---|---|---|---|---|---|---|
| Item | N | % | N | % | $\chi^2$ | df | |
| Education | | | | | <1 | 1 | n.s. |
| Not college graduate | 12 | 46.2 | 14 | 53.8 | | | |
| College graduate | 14 | 53.8 | 12 | 46.2 | | | |
| Axis I diagnosis | | | | | 3.00 | 4 | n.s. |
| None | 2 | 7.7 | 4 | 15.4 | | | |
| Dysthymia | 7 | 26.9 | 5 | 19.2 | | | |
| Major depression | 16 | 61.5 | 16 | 61.5 | | | |
| Bipolar, depressed | 1 | 3.8 | 0 | 0.0 | | | |
| Bipolar, mixed | 0 | 0.0 | 1 | 3.8 | | | |
| Axis II diagnosis | | | | | 3.03 | 7 | n.s. |
| Borderline | 15 | 57.7 | 16 | 61.5 | | | |
| Mixed | 6 | 23.1 | 6 | 23.1 | | | |
| Dependent | 1 | 3.8 | 1 | 3.8 | | | |
| Avoidant | 0 | 0.0 | 1 | 3.8 | | | |
| Histrionic | 1 | 3.8 | 0 | 0.0 | | | |
| Obsessive-compulsive | 1 | 3.8 | 1 | 3.8 | | | |
| Schizoid | 1 | 3.8 | 0 | 0.0 | | | |
| Schizotypal | 1 | 3.8 | 1 | 3.8 | | | |
| History of suicide attempts[a] | 21 | 80.8 | 19 | 73.1 | <1 | 1 | n.s. |

[a] The self-mutilators had made a mean of 3.0 (SD=3.1) suicide attempts; the nonmutilators had made a mean of 2.2 (SD=2.5) (t=1.10, df=47, n.s.).

For data analysis, two-group t tests were used to compare self-mutilators with control subjects on all continuous demographic, psychopathological, and biological measures. Chi-square tests were used to compare educational level, axis I diagnoses, axis II diagnoses, and rate of suicide attempts in the two groups. Pearson correlations were computed between self-mutilation and psychopathological variables and biological measures. All probability values are two-tailed. Because this study was exploratory in nature, multiple zero order correlations and t tests were performed, not accounting for the overall number of analyses. This process is designed to generate further areas of investigation.

## RESULTS

### *Measures of Psychopathology*

The total mean Hamilton depression scale score of the self-mutilators was significantly higher than that of the control subjects (table 2). This difference was accounted for by greater anxiety and somatization and greater cognitive disturbance rather than by vegetative factors. The two groups did not differ in their scores on the Beck Depression Inventory and the Beck Hopelessness Scale (table 2).

**TABLE 2. Scores on Measures of Psychopathology of Subjects With Personality Disorders Who Were or Were Not Self-Mutilators**

| | Self-Mutilators[a] | | Nonmutilators[a] | | Comparison[b] | |
|---|---|---|---|---|---|---|
| Measure | Mean | SD | Mean | SD | t | p |
| Hamilton Rating Scale for Depression | | | | | | |
| Total | 24.8 | 5.1 | 19.8 | 10.2 | 2.25 | ≤0.05 |

| MMPI psychopathic deviance | 28.8 | 4.2 | 24.5 | 4.1 | 3.68 | ≤0.001 |
| Buss-Durkee Inventory | 41.8 | 12.4 | 36.9 | 11.5 | 1.45 | n.s. |
| Sensation Seeking Scale | 18.2 | 7.1 | 18.1 | 6.5 | <1 | n.s. |

[a] The number of self-mutilators for whom scores were available ranged from 19 to 26; the number of nonmutilators for whom scores were available ranged from 16 to 26.

[b] Two-tailed t test.

Self-mutilators scored significantly higher or almost significantly higher than control subjects on all but two of the 11 subscales of the Schedule for Interviewing Borderlines (table 2). Self-mutilators also had significantly greater total aggression than control subjects on the measure of history of aggression (table 2). Self-mutilators were significantly more antisocial as determined by their mean score on the MMPI psychopathic deviance subscale (table 2). Self-mutilators and control subjects did not differ significantly on the mean total Buss-Durkee Inventory score (table 2) or on any mean subscale score. There were no group differences for the mean total Sensation Seeking Scale score (table 2) or on any mean subscale score.

Within the self-mutilator group, correlations were computed between the degree of self-mutilation and all other indexes of psychopathology (a total of 36 scale and subscale correlations). Although we found no significant difference between the two groups in impulsivity as measured by the Schedule for Interviewing Borderlines subscale, there was a significant positive correlation between the degree of self-mutilation and impulsivity within the self-mutilator group (r=0.54, N=26, p≤0.01). The degree of self-mutilation was also significantly correlated with inappropriate chronic anger (r=0.43, N=26, p≤0.05) and with the somatic anxiety item (r=0.46, N=24, p≤0.05) but not with the psychic anxiety item (r=0.16, N=24, n.s.) of the chronic anxiety subscale (r=0.34, N=24, p≤0.10). There was a significant negative correlation between the degree of self-mutilation and Beck Hopelessness Scale score (r=–0.43, N=23, p≤0.05). There was a nonsignificant trend toward a positive correlation between the degree of self-mutilation and the aggression score (r=0.37, N=24, p≤0.08). No other correlations between degree of self-mutilation and measures of psychopathology approached significance. Aggression and impulsivity scores were significantly positively correlated (r=0.61, N=24, p≤0.01).

### *Biological Measures*

In the self-mutilator group, there was a significant negative correlation between the degree of self-mutilation and $B_{max}$ and between impulsivity and $B_{max}$ (table 3). Aggression did not significantly correlate with any of the serotonergic measures in the self-mutilator group (table 3).

In the control group and in the total study group no significant correlation was found between the serotonergic measures and impulsivity or aggression (table 3).

The mean CSF 5-HIAA levels for the self-mutilators and nonmutilators were 19.4 (SD=9.7) and 20.2 (SD=9.7), respectively (t<1, df=36, n.s.). The respective mean values of $B_{max}$ for the two groups were 861.2 (SD=423.6) and 1004.9 (SD=502.5) (t<1, df=29, n.s.), and the respective mean values of $K_d$ were 1.7 (SD=0.6) and 1.6 (SD=1.0) (t<1, df=29, n.s.). Thus, self-mutilators and control subjects did not differ from each other on any measure of serotonergic function.

## DISCUSSION

Our study resulted in the following significant findings: 1) self-mutilators had more severe character pathology than diagnostically matched nonmutilators, 2) there was a significant positive correlation between the degree of self-mutilation and impulsivity, chronic anger, and somatic anxiety, 3) there was a significant negative correlation between the degree of self-mutilation and $B_{max}$ and between impulsivity and $B_{max}$. Because the two groups did not differ diagnostically regarding affective and personality disorders or in their suicide history, these findings can be more confidently attributed to self-mutilation per se.

The results delineate the affective profile of self-mutilators as individuals who suffer from more depression than control subjects according to the Hamilton depression scale but not the Beck Depression Inventory but do not suffer from greater hopelessness. We might speculate that the significant negative correlation between the degree of self-mutilation and hopelessness lends support to the conceptualization of self-mutilation as an act of self-healing through the transient restoration of more hopeful affect. The more striking finding, however, is the greater dysphoric affect, with anxiety, anger, emptiness, and rejection sensitivity, that characterized our self-mutilator group. Mounting anxiety has been clinically described as an important predictor in the escalating phase before the act of self-mutilation. Mounting anxiety may be either a direct precipitant of self-mutilation or the final common pathway to a variety of thoughts, affects, and experiences that trigger self-mutilating behavior. Relief of mounting anxiety has been cited as a reason for self-mutilation in 35% (9), 45% (8), and 86% (7) of self-mutilators sampled in different studies. In our study, chronic somatic anxiety was significantly correlated with the degree of self-mutilation, and self-mutilators had greater anxiety than control subjects on the Schedule for Interviewing Borderlines and the Hamilton depression scale.

The contribution of poor impulse control to acts of self-mutilation is supported by our finding of a significant positive correlation between impulsivity and the degree of self-mutilation. However, impulsivity as measured by the Schedule for Interviewing Borderlines did not differ between self-mutilators and control subjects. Thus, what distinguishes self-mutilators is not their impulsivity, which they share with other individuals with severe personality disorders, but their greater aggression, which when combined with poor impulse control takes the form of self-mutilation rather than less aggressive impulsive behaviors assessed by the Schedule for Interviewing Borderlines, such as gambling, spending, promiscuity, overeating, and oversleeping.

This hypothesis is strongly supported by our finding of greater aggressive behavior, sociopathic tendencies, and chronic anger in the self-mutilators. Bennum (8) reported similar findings in a comparison of self-mutilators, nonmutilating depressed patients, and normal control subjects. Self-mutilators and depressed patients did not differ in overall Beck Depression Inventory scores, and both had greater depression than normal control subjects. However, self-mutilators had greater outwardly directed hostility than depressed patients, although they had comparable levels of inwardly directed hostility. Indeed, before and during the act of self-mutilation, 18%–45% of patients in various studies (7–9) reported anger toward themselves, and 10%–32% reported anger toward others. In our study group of self-mutilators, chronic inappropriate anger was significantly correlated with the degree of self-mutilation. It is notable that the two major affects that have previously been found to characterize patients' emotional states at the time of self-mutilation—anger and anxiety—were also found to be longstanding traits differentiating self-mutilators and nonmutilators in the current study.

Of note is the overall greater degree of psychopathology in the self-mutilator group with regard to multiple borderline traits compared with the control subjects matched for the presence and type of personality disorder. This could indicate that self-mutilation in itself may be a marker for more severe borderline character pathology and thus may have prognostic implications that extend beyond the treatment of the self-mutilative aspect per se. Alternatively, the combination of impulsivity and aggression and the variety of personality disorders characteristic of the self-mutilator group raise the argument that self-mutilation might best be viewed as a distinct axis I impulse control disorder, as intermittent explosive disorder, kleptomania, pathological gambling, pyromania, and trichotillomania are currently viewed in *DSM-III-R* (27, 28). Furthermore, impulse control disorders could be subdivided into aggressive and nonaggressive types (e.g., self-mutilation and kleptomania, respectively). In this light, self-mutilation could be conceptualized as not only a symptom specific to borderline personality disorder but an impulsive syndrome that may be more common in but not limited to

**TABLE 3. Correlations Between Biological Variables and Self-Mutilation, Impulsivity, and Aggression in Subjects With Personality Disorders Who Were or Were Not Self-Mutilators[a]**

patients with borderline personality disorder, similar to substance abuse and bulimia.

From a biological perspective, our main finding was the significant negative correlation between degree of self-mutilation and imipramine binding and between impulsivity and imipramine binding. Platelets have been viewed as an analog of the serotonergic neuron because their uptake, storage, and release of serotonin are similar to those of the presynaptic neurons. A smaller number of imipramine binding sites has been reported in a variety of psychiatric conditions and may reflect central serotonergic dysfunction with reduced presynaptic serotonin release. A few studies have specifically linked this serotonergic index to disorders of aggression and impulsivity. Stoff et al. (16) found significantly fewer platelet imipramine binding sites in prepubertal children who had conduct disorders with or without attention deficit disorder with hyperactivity than in normal control subjects. Stoff et al. also found a significant negative correlation between binding sites and externalizing and aggressive behavior in adolescents who had histories of assaultive actions. Birmaher et al. (17) studied children who had conduct disorders with or without attention deficit disorder with hyperactivity but who did not have depression and suicidality and found an inverse correlation between impulsive, hostile, and aggressive behaviors and platelet imipramine binding sites. Similar to these two studies, our study links platelet imipramine binding to another form of aggressive and impulsive behavior, self-mutilation. The association between the degree of self-mutilation and imipramine binding in the absence of an absolute difference in serotonergic measures between self-mutilators and control subjects raises the issue of whether serotonergic dysfunction may be more important in terms of the severity of self-mutilation rather than the presence or absence of this behavior. Of interest, when we excluded all patients with histories of suicide attempts from both groups in order to control for the possibly confounding association between serotonin and suicide, the three self-mutilators had mean CSF 5-HIAA levels that were 44% lower (mean=16.7, SD=4.2) than those of the five non-mutilators (mean=30.1, SD=13.0). This relationship merits future investigation with larger samples.

In summary, our initial psychological results highlight the contribution of severe character pathology, impulsivity, aggression, anxiety, and anger to self-mutilating behavior. Our initial biological results indicate that serotonergic dysfunction may facilitate self-mutilation, as has been shown for other impulsive and aggressive behaviors. Our relatively small sample sizes, especially for the biological measures, as well as the mild to moderate mean frequency of self-mutilation in our patient group, may have limited the strength of our findings. Therefore, a prospective study of a larger group of subjects with more acute, severe, and frequent acts of self-mutilation, as well as development of a standardized instrument to operationally assess self-mutilation, are warranted to further enhance our understanding of self-mutilation from both a psychological and a biological perspective.

# Prevalence of Mental Disorder in 88 Morbidly Obese Bariatric Clinic Patients

Donald W. Black, M.D., Risë B. Goldstein, M.S.W., M.P.H., and Edward E. Mason, M.D.

*Objective: The authors sought to determine the association between mental disorder and morbid obesity, defined as weight at least 100% or 100 lb over ideal body weight. Method: Eighty-eight morbidly obese subjects who had come to a tertiary care center surgery clinic requesting vertical banded gastroplasty were systematically interviewed with the National Institute of Mental Health Diagnostic Interview Schedule (DIS) and the Structured Interview for DSM-III Personality Disorders. A comparison group of 76 psychiatrically normal subjects who were matched in age (within 5 years) and gender to the morbidly obese subjects were also interviewed. Results: Most of the morbidly obese subjects were women, were of low socioeconomic status as indicated by method of payment for medical care, weighed more than 300 lb, and had been obese for more than 14 years. The morbidly obese subjects were more likely than the comparison group to have a lifetime history of mood disorders, anxiety disorders, bulimia, and tobacco dependence. The morbidly obese subjects were also more likely to meet diagnostic criteria for one or more personality disorders. Conclusions: Substantial psychopathology exists in morbidly obese individuals requesting gastroplasty, a finding that has important clinical implications.*

(Am J Psychiatry 1992; 149:227–234)

Morbid obesity, defined as weight at least 100% or 100 lb (45 kg) over ideal body weight, is a major health problem (1, 2). It is associated with substantial morbidity and excessive mortality as an established risk factor for cardiovascular, metabolic, neoplastic, and orthopedic conditions (1). Because of the relationship of morbid obesity to serious illness, attention has been focused on methods for producing weight loss. Conventional approaches for the management of obesity (e.g., dieting) have proven unsuccessful for the morbidly obese, leading to the development of surgical alternatives. Gastric restriction procedures, particularly vertical banded gastroplasty, have become the most common surgical procedures for the treatment of morbid obesity. In vertical banded gastroplasty, a small gastric pouch is created that physically limits the patient's caloric intake and gives the patient a sensation of satiety (2).

Despite renewed interest in the physiology, etiology, and treatment of obesity, little has been learned over the past two decades about its relationship to specific emotional disturbances. Studies of individuals with mild to moderate obesity suggest that they are no more likely than others to suffer from mental disorders (3). Studies of the morbidly obese, however, have been less conclusive. Since 1960, 15 articles (4–18) have reported rates of mental illness in morbidly obese individuals. The results varied markedly from one study to another for both rates and types of mental disorders. For instance, the rates for depression ranged from 4% to 80%, and the rates for personality disorder ranged from 15% to 83% (table 1). The 15 studies, along with the results of the present study, are summarized in table 1.

Castelnuovo-Tedesco (19) concluded in 1987 that although mild to moderate depression or personality disturbance was commonplace among the morbidly obese, severe psychopathology including "psychosis or crippling neurosis" rarely seemed to occur in this group. However, it is difficult to draw sound conclusions from the studies he reviewed because their methods differed substantially. All relevant studies are flawed to some extent. Other than our own current study, 12 of the 15 studies reviewed in table 1 specified criteria for morbid obesity (4, 5, 7, 8, 10, 11, 13–18), seven specified criteria for the diagnosis of mental disorders (12–18), three used standardized interviews or assessments (15, 17, 18), and one included a comparison group (17). Further, many of the studies used small and possibly biased groups of subjects. For instance, in one study (5), the subjects were seen in a psychosomatic

clinic; in another (6), the subjects had all been referred for psychiatric evaluation.

With the shortcomings of these studies in mind, we set out to design a project to investigate the prevalence of psychopathology in the morbidly obese. The subjects were outpatients seen at our university's department of surgery for evaluation for vertical banded gastroplasty. Subjects were carefully assessed for both major mental disorders (*DSM-III* axis I) and personality disorders (*DSM-III* axis II) by using structured instruments of established reliability. We were interested in learning whether rates of major mental illnesses and personality disorders were greater among the morbidly obese than would be expected in the community.

It is important to understand the extent of psychopathology in the morbidly obese. The number of individuals undergoing vertical banded gastroplasty is substantial (12), and the presence of a psychiatric disorder may be associated with poor compliance with medical treatment and thus may impede postsurgical recovery. In addition, psychiatric disorder may contribute to poor outcome in terms of weight loss. By learning about preexisting psychiatric disorders, the treatment team is better prepared to modify its approach to improve compliance, reduce the number of complications, and, one hopes, to boost weight loss. Furthermore, if the mere presence of psychopathology is used to exclude patients from receiving vertical banded gastroplasty (as it has been used to exclude patients from receiving heart transplants [20]), then it behooves us to study correlations between mental disorder and outcome. We will present outcome data in subsequent reports.

## METHOD

### *Subjects*

Eighty-eight patients seen at our university's surgery clinic for consultation regarding vertical banded gastroplasty were recruited between January 1987 and June 1989. Patients were eligible for this study if they were at least 18 years old and at least 100% or 100 lb (45 kg) over their desirable weight according to actuarial tables (21). Patients with clinically apparent mental retardation or organic brain syndromes were not eligible for the study because these disorders complicate the assessment of other forms of psychopathology. No subjects were excluded on this basis, however.

Intake was not consecutive because our trained rater was not available to attend the bariatric clinic each week. However, over the 30-month recruitment period, only three individuals invited to participate refused to do so.

### *Assessments*

Morbidly obese subjects were invited to participate in a study of the "psychological characteristics or emotional adjustment of morbidly obese persons." After giving informed consent, subjects were evaluated by a trained rater using 1) the National Institute of Mental Health Diagnostic Interview Schedule (DIS) (22), which has established adequate reliability for diagnosing major mental disorders according to *DSM-III* criteria, 2) an additional semistructured interview that we developed covering demographic and clinical information, such as family history and age at onset of obesity, and 3) the Personality Diagnostic Questionnaire (PDQ) (23), a self-report instrument used to assess *DSM-III* personality disorders. Starting in November of 1987, the Structured Interview for DSM-III Personality Disorders (24) was added to the assessment battery to provide a more thorough personality assessment. This instrument has shown adequate reliability for many of the *DSM-III* personality disorders.

### *Comparison Group*

Subjects used for comparison were recruited in the course of another study. As part of a family study of

**TABLE 2. Method of Medical Care Payment of 88 Morbidly Obese Subjects**

| Method of Payment | Number | Percent |
|---|---|---|
| Medicaid or Medicare | 40 | 45.5 |
| Public aid | 12 | 13.6 |
| Blue Cross/Blue Shield | 21 | 23.9 |
| Private insurance | 13 | 14.8 |
| Unknown | 2 | 2.3 |

obsessive-compulsive disorder, we identified 33 psychiatrically normal subjects who had been screened with the Schedule for Affective Disorders and Schizophrenia—Lifetime Version (25). We then systematically interviewed all available first-degree relatives (N=129) of these normal subjects using the DIS (22) and the Structured Interview for DSM-III Personality Disorders (24). These relatives made up a relatively unbiased community sample. From these 129 potential subjects, we identified 76 who were matched in age (within 5 years) and gender to the morbidly obese subjects.

### *Statistical Analysis*

Categorical data were analyzed by using the chi-square statistic and, when necessary, Fisher's exact test. We analyzed our continuous data by using the nonparametric Wilcoxon rank sum test. Odds ratios were calculated with 95% confidence intervals for individual diagnoses and diagnostic categories (26). The odds ratio is an estimate of the magnitude of the association between the presence of two characteristics, such as morbid obesity and major depression. For example, an odds ratio of 1 is interpreted as evidence of no association, but an odds ratio of 4.0 would indicate that subjects with morbid obesity would be four times more likely than comparison subjects to have major depression. We report crude (i.e., unadjusted for age and gender) odds radios because our data showed that these variables did not confound the association between obesity and mental disorder.

## RESULTS

Eighty-eight subjects with morbid obesity were included in the study; 18 (20.5%) were men, and 70 (79.5%) were women. Their mean age was 36.1 years (SD=10.3); men had a mean age of 34.2 (SD=10.9), and women had a mean age of 36.6 (SD=10.2). Of the 76 subjects in the comparison group, 18 (23.7%) were men and 58 (76.3%) were women; their mean age was 36.5 (SD=11.2). The age and gender distributions of the comparison subjects were comparable to those of the morbidly obese subjects. Eighty-six (97.7%) of the morbidly obese subjects were white, and two (2.3%) of the obese subjects were black.

The baseline mean weight of the morbidly obese subjects was 141.3 kg (SD=28.3); the mean weight of the men was 170.8 kg (SD=26.8), and the mean weight of the women was 133.5 kg (SD=23.3). The mean age at onset of obesity for the morbidly obese subjects was 11.5 (SD=9.9) years; mean age at onset for the men was 8.9 (SD=7.5), and mean age at onset for the women was 11.8 (SD=10.3). The methods of payment for medical care of the morbidly obese subjects are presented in table 2.

The lifetime prevalence of psychiatric disorders in the morbidly obese subjects and the comparison subjects is presented in table 3. These percentages are based on definite cases of the disorders according to DIS results; subjects could qualify for more than one diagnosis. The morbidly obese subjects had a significantly higher prevalence of mood disorders (especially major depression), anxiety disorders (especially agoraphobia, simple phobia, and posttraumatic stress disorder [PTSD]), bulimia, and tobacco dependence than the comparison subjects. If all disorders measured by the DIS are totaled, 84% of the morbidly obese subjects and 59% of the comparison group met criteria for at least one disorder.

The obese subjects were significantly more likely to have one or more psychiatric disorders (table 4). They had a mean of 2.1 disorders (SD=1.5) and a median of 2, compared with a mean of 0.9 (SD=1.0) and a median of 1 for the comparison subjects (Z=–5.63, p=0.000000009, Wilcoxon rank sum test).

The frequency distributions of personality disorders for the two groups are presented in table 5. The obese subjects for this analysis included only the 46 patients who were given the Structured Interview for DSM-III Personality Disorders. Their mean age was 37.0 years (SD=10.1), and 37 (80.4%) were women; their age and gender distributions were comparable to those of the morbidly obese group as a whole. Frequencies were based on definite diagnoses of the disorders according to the Structured Interview for DSM-III Personality Disorders results; subjects could qualify for more than one personality disorder diagnosis. Morbidly obese subjects were significantly more likely than subjects in the comparison group to manifest "eccentric" (cluster A), "dramatic" (cluster B) (except for narcissistic), and "anxious" (cluster C) (especially avoidant and passive-aggressive) personality disorders.

The morbidly obese subjects were also more likely than comparison subjects to exhibit symptoms of personality disorder and to meet criteria for more than one disorder according to the Structured Interview for DSM-III Personality Disorders (table 6). In fact, 72% (N=33) of the 46 of morbidly obese subjects met criteria for at least one personality disorder, compared with only 37% (N=28) of the 76 comparison subjects. The 46 morbidly obese subjects had a mean of 27.2 symptoms (SD=12.9) and a median of 29, compared with a mean of 14.2 (SD=8.8) and a median of 11.5 for the comparison subjects (Z=5.41, p=0.00000003, Wilcoxon rank sum test). They had a mean of 1.7 personality disorders (SD=1.5) and a median of 1.5, compared with a mean of 0.6 (SD=0.9) and a median of 0 for the comparison subjects (Z=4.58, p=0.000002, Wilcoxon Rank Sum test).

**TABLE 3. Lifetime Prevalence of Major Mental Disorders in Morbidly Obese Subjects and Comparison Subjects**

## DISCUSSION

Several conclusions can be drawn about the morbidly obese subjects who came to our bariatric clinic. Most were women. They tended to be of low socioeconomic status as indicated by the method of payment for medical care, they had been obese for more than 14 years, and they weighed, on average, more than 140 kg (308 lb). Careful assessment showed that the morbidly obese subjects had higher rates of mood disorders, anxiety disorders, bulimia, tobacco dependence, and personality disorders than a comparison group from the community. These findings were supported by the finding of an excess number of DIS and Structured Interview for DSM-III Personality Disorders diagnoses in the morbidly obese. Our findings directly contradict those of Stunkard et al. (1), who concluded that the prevalence of psychiatric disorders among morbidly obese individuals does not significantly differ from that in the general population. Their conclusion was based on a review of two papers (13, 15), neither of which was designed to compare prevalence of mental disorder in the morbidly obese with community norms. In fact, our morbidly obese subjects clearly experienced substantial and excessive psychological distress.

Although experts agree that a distorted body image and preoccupation with weight are cardinal features of morbidly obese patients, there has been little consensus on the degree and type of emotional pathology seen in these patients (1, 19). Early studies emphasized that although obese individuals were free of severe psychopathology (e.g., psychosis), they were often prone to neurosis or personality disturbances believed by psychodynamically oriented clinicians to result from oral fixation or from regression after failure to master oedipal situations (19). More recent studies have focused on prevalence rates of specific mental illnesses. Perhaps reflecting the ease with which this particular group can be studied, most reports on the psychological state of the morbidly obese have been carried out on patients who are seeking surgical treatments of obesity or are referred for such treatments.

Although our study found a high prevalence of specific mental disorders in the morbidly obese, it cannot answer the question of why these patients suffer psychological distress. It is possible that the morbidly obese come from families genetically loaded for mental illness and that this genetic vulnerability (or the conse-

quence of growing up in a disorganized and abusive home as a result of parental mental illness) leads to the development of emotional disorders such as major depression. There is evidence that the families of obese individuals (not necessarily morbidly obese individuals) are emotionally disturbed (27, 28). Alternatively, morbid obesity may itself lead to depression, anxiety, or other disturbances brought on by the considerable ostracism morbidly obese individuals experience. In a society that values youth, beauty, and slimness, the obese are made to feel unattractive and inadequate. It is possible that a combination of genetic and social influences have jointly led to these emotional disorders.

Specific anxiety disorders that were more frequent in the morbidly obese subjects included agoraphobia, simple phobia, and PTSD. It is tempting to speculate that morbidly obese individuals develop phobic avoidance in response to social cues such as stares or whispered comments, but other factors may be operating as well. PTSD, uncommon in the general population (29), usually results (in women) from the effects of a violent assault or rape. All morbidly obese subjects meeting criteria for PTSD in our study were women, leading us to speculate that morbidly obese women suffer from substantial physical or sexual abuse. This abuse may be interpreted as an extreme form of the social stigmatization that they suffer as a consequence of their obesity. On the other hand, victims of abuse or trauma may turn to food for solace.

Our findings on personality disorders based on the Structured Interview for DSM-III Personality Disorders support an earlier pilot study (17). In that report, personality was assessed in 38 morbidly obese individuals (a subset of the current sample) by using a self-report instrument, the PDQ. Contrary to the findings of earlier studies (7, 10, 14), dependent and passive-aggressive personality were not the most frequent disorders. Our pilot study showed that eccentric and dramatic cluster disorders, especially borderline personality, were the most common personality disturbances in morbidly obese subjects. In the current study, all three personality disorder clusters were significantly more frequent in the morbidly obese than in the comparison group, especially the eccentric and dramatic clusters. Since early investigators tended to base their diagnoses on clinical interviews, and all predated *DSM-III*, direct comparisons with our findings are inappropriate.

As we have pointed out elsewhere (17), the distorted self-image and identity that many morbidly obese individuals suffer from could lead to an endorsement of the criteria for a personality disorder. For example, according to *DSM-III-R* criteria, the morbidly obese may understandably feel a tendency to "read hidden . . . meanings into benign remarks" (criteria for paranoid personality), to have "extreme discomfort in social situations" (criteria for schizotypal personality), to choose "solitary activities" (criteria for schizoid personality), to have "impulsiveness in . . . areas that are self-damaging" such as binge eating and "persistent identity disturbances" (criteria for borderline personality), or be "easily hurt by criticism or disapproval" (criteria for avoidant personality). Whether this endorsement of criteria reflects enduring maladjustment, which is expected in a personality disorder, or represents a transient disturbance associated with the morbid obesity that will correct with weight loss is open to question. Therefore, it will be important to learn whether weight loss following vertical banded gastroplasty leads to the abandonment of abnormal personality traits and is associated with a concomitant improvement in PDQ or Structured Interview for DSM-III Personality Disorders scores. Some believe that the endorsement of certain criteria is a reflection of the morbid obesity rather than of the individual. However, if diagnostic criteria are to have any meaning, they need to be applied regardless of presumed etiology.

Other disorders that were more frequent than expected in our morbidly obese subjects were bulimia and tobacco dependence. Although morbid obesity is not recognized as an eating disorder in *DSM-III-R*, it shares certain similarities with bulimia nervosa (30), such as a lack of control over eating and a preoccupation with body image. The finding of excess tobacco dependence may be confounded by social class because, like our morbidly obese subjects, smokers are predominantly from the lower social classes (31). Possibly, the obese take up smoking cigarettes as a substitute for eating, only to find themselves addicted to them.

Although the data showed that the morbidly obese suffer more psychopathology than a comparison group in a Midwest community, these findings cannot tell us whether the pattern of psychopathology is unique to the morbidly obese. A surgical or medically ill comparison group could help to solve that question. Further, the findings may apply only to morbidly obese individuals who seek surgery, since those who do not seek surgery may have rates of mental disorder no different from what would be expected in the general population. However, the vertical banded gastroplasty population is substantial, so our data remain important even if they apply only to that specific group of patients.

Additional limitations of our study need to be acknowledged. Although the study group was relatively large, the low base rate of most mental disorders means that some of the individual cell samples (e.g., subjects with panic disorder) were small. A larger study group would have reduced the possibility of a type II error (i.e., accepting the null hypothesis when it is false) and helped to minimize the lack of precision of the odds ratios indicated by their wide confidence intervals. Error could also have arisen from rater bias or from errors in the administration of the assessment instruments, since the data reported came primarily from interviews. Although the DIS and the Structured Interview for DSM-III Personality Disorders are fully structured, and the same person interviewed both morbidly obese and comparison subjects, the rater was aware of the study objectives. Future investigations should be designed to ensure that raters are blind to study purposes.

Most of our patients were white women of low socioeconomic status who came to a tertiary care facility for vertical banded gastroplasty. Our subjects may therefore not be representative of morbidly obese individuals in general or of those who seek treatment at other centers. However, the sociodemographic profile of our study subjects was similar to that reported by other researchers in a tertiary care setting (14).

It might be argued that the way the comparison group was selected helped to eliminate mentally ill individuals, thereby exaggerating the differences between the groups. In fact, the frequency of mental disorders in the comparison group was comparable to national rates reported in the Epidemiologic Catchment Area study (32), a finding that supports their validity.

The effect of psychiatric history and of specific psychiatric disorders on the outcome of patients who have bariatric surgery remains to be determined. Follow-up of our study subjects and future studies of bariatric patients should provide answers to these questions.

The findings from the current study may help lead to a better understanding of and care for morbidly obese patients. Studies such as ours may eventually help to match patients with obesity treatments and aid in the design of follow-up plans tailored to individual needs. Improvements in care would likely help to boost compliance, minimize complications, and maximize weight loss. These advances could include medication regimens, educational and counseling efforts tailored to specific psychiatric disorders, frequent clinic visits to provide support and encouragement, and appropriate psychiatric referral.

# Patients Who Use Drugs During Inpatient Substance Abuse Treatment

Shelly F. Greenfield, M.D., Roger D. Weiss, M.D., and Margaret L. Griffin, Ph.D.

*Objective: Drug use by patients during inpatient substance abuse treatment is frequently a cause of premature hospital discharge. The authors examined the histories of patients who used drugs while in inpatient substance abuse treatment, the methods used to detect drug use, and the temporal relationship of drug use episodes. Method: The authors reviewed the charts of patients admitted consecutively to an inpatient substance abuse treatment unit between 1981 and 1988. Of 729 patients, 42 were found to have used drugs while receiving inpatient treatment. The diagnoses and clinical histories of these 42 patients were compared with those of all other patients. Methods of detection and circumstances of drug use were recorded, and drug use episodes were plotted on a time line that was examined for temporal clustering. Results: Significantly more of the patients who used drugs during inpatient substance abuse treatment had primarily used heroin or methadone before treatment. Random urine screens, self-report, and staff observation together detected approximately 85% of the patients who used drugs during treatment. Episodes of drug use did cluster in time, but within clusters the hospital stays of the patients who used drugs did not necessarily overlap. Conclusions: Temporal clustering of drug use episodes may occur because drug use by one patient heralds drug availability and stimulates craving in other inpatients. Clinicians should be aware that one episode of drug use may be followed by others. Multiple detection methods, including random comprehensive urine screens, should be used to test for drug use on inpatient units.*
(Am J Psychiatry 1992; 149:235–239)

Drug use by patients during inpatient substance abuse treatment is the reason many patients are prematurely discharged from the hospital or drop out of treatment (1, 2). Although numerous studies have investigated the characteristics of patients who are discharged against medical advice (3–11) or drop out of drug abuse treatment (12–18), to our knowledge only one previous study (19) has examined drug use among inpatients in drug abuse treatment facilities, and that study investigated only cocaine use. We retrospectively reviewed data collected over 8 years and identified all patients on an inpatient substance abuse unit who used drugs during their treatment. The study was done to answer the following questions: 1) Were there any features among the patients' clinical, diagnostic, and substance abuse histories that characterized patients who used drugs while in inpatient substance abuse treatment? 2) Were the episodes of drug use related to each other in time? and 3) Which method was most effective in detecting drug use during inpatient substance abuse treatment?

## METHOD

### *Setting and Subjects*

We collected data on 729 patients admitted consecutively between 1981 and 1988 to an alcohol and drug abuse treatment unit in an urban private, nonprofit psychiatric hospital. The majority of patients were white and from middle and upper-middle socioeconomic levels. From 1981 to 1985 the unit treated only patients with primary drug dependence. In January 1986 the unit also began accepting patients with primary alcoholism, who previously had been treated on a separate alcoholism unit in the hospital.

Patients admitted to the unit participated in a multidis-

ciplinary substance abuse treatment program; the average length of stay was approximately 4 weeks. Supervised random urine toxicologic screens were obtained at least three times a week to ensure drug-free status throughout this period. The initial analysis of urine samples was by means of the enzyme-multiplied immunoassay technique (EMIT). The presence of drugs was confirmed with gas chromatography/mass spectrometry.

We reviewed hospital records to identify all patients who had brought drugs onto the unit, used drugs on the unit, or used drugs while on passes during their hospital stays. Virtually all such patients were either discharged or transferred to other treatment settings after discovery of their drug use.

### Data Collection

One of the physician investigators (S.F.G.) used a standardized chart audit form to collect the following information about the episodes of drug use during treatment: 1) type of drug used, 2) date of drug use, 3) whether the drug was used in the presence of other patients, and 4) method of detection.

The patients identified as having used drugs were compared with all other patients admitted to the unit on several sociodemographic, clinical, and substance abuse history variables that were routinely collected at admission with a 287-item self-administered questionnaire (20). The drug users' admission scores on the Social Adjustment Scale (21), revised 90-item Symptom Checklist (SCL-90-R) (22), Hamilton Rating Scale for Depression (23), and Beck Depression Inventory (24) were also compared with the scores of all other patients admitted to the unit.

For patients who had abused multiple substances before admission, we defined the primary drug of abuse as the drug that caused the greatest difficulties for the patient before admission. This was determined through clinical interview of the patient by the unit psychiatrist, the patient's response on a structured substance abuse history questionnaire, and information about the patient gathered from family members by the unit's social workers.

On the basis of repeated clinical interviews and observation of the patients' behavior on the unit, diagnoses based on *DSM-III* criteria were made at discharge by one of us (R.D.W.). An independent diagnostic assessment was carried out by a second psychiatrist, who was not involved with the research and who met with the patient three to four times each week throughout the hospital stay. When the two diagnoses differed, a consensus diagnosis was made, and only one diagnosis was recorded. Because of the difficulty in evaluating past psychiatric symptoms in the context of concurrent heavy drug use, a patient received an axis I diagnosis other than substance abuse only if he or she were currently ill and had previously fulfilled the diagnostic criteria for that disorder while drug free. Antisocial personality disorder was the only axis II disorder assessed because of the particular difficulty inherent in distinguishing between addiction-related behaviors and enduring personality characteristics. The reliability and validity of the antisocial personality disorder diagnosis have been rigorously tested (25), and the inclusion of age at onset in the diagnostic criteria helps distinguish symptoms of this disorder from behavior related to drug abuse.

### Data Analysis

Statistical significance was determined with the chi-square test for categorical data. A two-tailed Student's t test for independent samples was used for comparison of means. Episodes of drug use during treatment were plotted on a time line that was examined for apparent clustering of data points. The apparent clusters were then analyzed by using a Poisson distribution (26, 27) to estimate expected rates of drug use for each 3-month interval.

## RESULTS

Of the 729 patients admitted consecutively to the inpatient substance abuse unit, 42 patients (5.8%) used drugs during inpatient treatment. The sex, marital status, and employment status of these patients and those who did not use drugs during treatment are presented in table 1. The two groups did not differ significantly on any of these three variables. However, the mean age of the drug users (mean=29.8 years, SD=5.9) was significantly lower than that of the patients who did not use drugs (mean=31.8 years, SD=8.2) ($t=2.05$, $df=52.05$, $p \le 0.005$).

Among the total group of patients admitted to the alcohol and drug abuse treatment unit during the study period, the primary drugs of abuse were opioids for 34% of the patients, cocaine for 27%, alcohol for 12%, marijuana for 4%, benzodiazepines for 3%, and other drugs for 20%. As shown in table 2, the percentage of patients for whom opioids, particularly heroin and

methadone, were the primary drugs of abuse was significantly higher among the patients who used drugs during treatment than among the patients who did not.

When we examined the data on substance abuse history, social adjustment, and psychiatric symptoms, we found that the mean age at first heavy drug use was lower among the patients who used drugs during treatment (mean=21.7 years, SD=3.9) than among the patients who did not (mean=23.8 years, SD=7.8) (t=2.34, df=26.72, $p \leq 0.03$). There were no differences between the two groups on any measure of current psychiatric symptoms or social adjustment. Twenty-three of the 42 drug users stayed in the hospital long enough for a diagnostic evaluation to be completed. The diagnosis of antisocial personality disorder was twice as common among this group as among the abstainers (35% and 16%, respectively; $\chi^2$=6.95, df=1, $p \leq 0.01$).

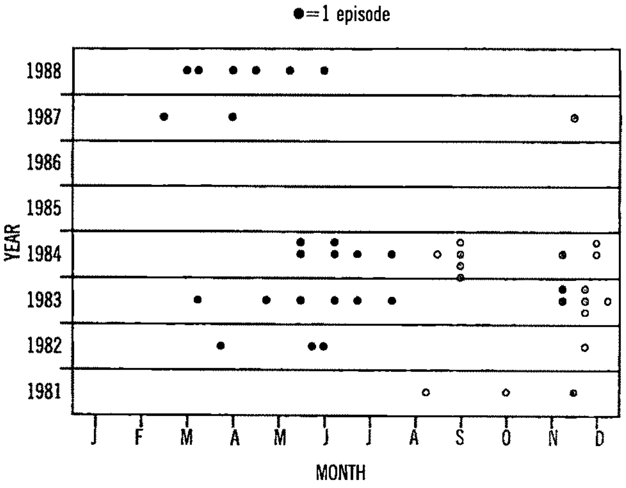
In examining patterns of drug use during treatment, we found that more than one-half of the drug users (N=23, 53%) used drugs that were not their primary drugs of abuse before admission. Drug use was initially detected by a random urine toxicologic screen in 38% of the cases (N=16), by staff observation that triggered a urine screen in 26% (N=11), by the patient's telling staff in 21% (N=9), and by reports from other patients in 10% (N=4). In two cases, it was not clear which method of detection was used. Of the 33 patients whose drug use was discovered by means other than their own admission, 19 patients (58%) admitted their drug use once confronted by staff.

Although no individual patient used drugs with any other individual patient during treatment, the episodes of drug use did cluster in time, as illustrated by figure 1. A Poisson analysis of the expected versus observed episodes demonstrated that the clustering was not attributable to chance alone ($\chi^2$=19.78, df=3, $p \leq 0.0002$). However, within clusters the hospital stays of the patients who used drugs did not necessarily overlap.

## DISCUSSION

Our findings suggest that for our subjects primary opioid abuse, especially heroin or methadone abuse, was a risk factor for drug use during inpatient treatment. Although the users during treatment were significantly younger at the time of treatment and at onset of drug abuse, the actual differences were probably too small to be clinically significant. The diagnosis of antisocial personality disorder was also more prevalent among those who used drugs during treatment.

**FIGURE 1. Temporal Distribution of Episodes of Drug Use by Patients During Inpatient Substance Abuse Treatment Over 8 Years**



In addition to these individual patient characteristics, we noted that the episodes of drug use on the substance abuse treatment unit tended to cluster in time. Interestingly, in each cluster the hospital stays of the inpatients who used drugs during treatment did not necessarily overlap with one another, and no patient who used drugs during treatment did so with another patient. This clustering was, therefore, not solely the result of direct transmission of drugs from one patient to another. Rather, a history of recent drug use on the unit served as a risk factor for drug use by other patients on the unit. Our findings are consistent with observations by Meyer and Mirin (28), who noted that drug craving on a heroin research ward was highly correlated with the subjects' perception of drug availability. In our study, the discussions by patients and staff about a former inpatient's relapse on the unit may have heralded drug availability to other inpatients, thus stimulating craving and leading to additional episodes of drug use on the unit.

Magura et al. (29) noted the complementary nature of self-report and urine screens in detecting illicit drug use in outpatient methadone treatment programs. Our results suggest that in inpatient substance abuse treatment staff observation is a third important method of detection. In fact, the three methods—supervised random urine screens, patient self-report, and staff observation—were complementary, together detecting approximately 85% of the patients who used drugs during treatment.

It is noteworthy that more than one-half of the patients who used drugs during treatment used substances other than their primary drugs of abuse. This argues for the use of comprehensive toxicologic screens for detection of drug use during treatment, rather than testing urine samples for only the patient's primary substance of abuse.

This study has several limitations. In an attempt to distinguish between coexisting psychopathology and the sequelae of drug abuse, we used two clinicians and multiple interviews to establish a consensus diagnosis, also using longitudinal clinical observations and historical data gathered from family members. Our diagnostic method has both strengths and weaknesses; an extended observation period, coupled with multiple sources of data, has been found to enhance validity in research (30–32). In addition, despite the evidence supporting the general utility of structured interviews, such as the Diagnostic Interview Schedule (33) and the Schedule for Affective Disorders and Schizophrenia (34), several studies (35–37) have shown the limitations of these instruments in the diagnosis of psychiatric disorders in substance abusers. However, because clinical interviews are less structured and may be less comprehensive than standardized instruments, we may have underdiagnosed some disorders.

Because of inadequate information, diagnoses other than substance abuse were made for only a limited number of the patients who used drugs during treatment, thus making our comparison with the abstainers potentially less reliable. Because diagnoses were made at discharge, after the detection of inpatient drug use, it is possible that the diagnosis of antisocial personality disorder in particular was subject to rater bias; this would lead to an overestimation of antisocial personality disorder in those who used drugs during treatment. The possibility of false positive urine tests in our study is remote because we used gas chromatography/mass spectrometry to confirm positive screens (38, 39). Finally, the results of this study may not be generalizable to groups whose socioeconomic characteristics, distribution of drugs of choice, or treatment setting differ substantially from those of our subjects.

These results do suggest that it is important to use multiple, complementary methods to detect drug use during treatment. They should include supervised random urine screens, staff observation, and patient self-report. The urine screen should be comprehensive and not limited to the primary drug of abuse. For patients addicted to a variety of substances, dependence on heroin or methadone may be a risk factor for drug use during inpatient treatment. Finally, clinicians should be advised that one episode of drug use on an inpatient substance abuse unit may be followed by others.

# Now Is the Time to Retire the Term "Organic Mental Disorders"

Robert L. Spitzer, M.D., Michael B. First, M.D., Janet B.W. Williams, D.S.W.,
Kenneth Kendler, M.D., Harold Alan Pincus, M.D., and Gary Tucker, M.D.

*The organic/nonorganic distinction in contemporary classifications of mental disorders such as* DSM-III *and* DSM-III-R *has important prognostic and treatment implications, because it directs the clinician to pay special attention to the possibility of an underlying "physical" disorder as the cause of the mental disturbance. However, the term "organic" raises serious and intractable problems, since the connotative meaning of the term always returns to its historical roots, which imply an outmoded functional/structural, psychological/biological, and mind/body dualism. The authors present a proposal being considered for* DSM-IV *that would eliminate the term "organic" and reorganize the classification of organic mental disorders. Disorders previously referred to as "organic mental disorders" would be renamed as either "secondary disorders" (if they are due to "physical" disorders) or "substance-induced disorders." The entire classification of mental disorders would be reorganized to distribute the secondary and substance-induced disorders into the major groups with which they share phenomenology. The traditional organic mental disorders—delirium, dementia, and amnestic disorder—would be grouped together under the rubric of "cognitive impairment disorders." While acknowledging problems with the suggested new terminology and reorganization of the classification, the authors argue that the potential benefits of the proposal for clarity and for facilitating differential diagnosis justify putting to rest the familiar but now anachronistic term "organic mental disorders."*

(Am J Psychiatry 1992; 149:240–244)

> The antithesis between "organic" and "functional" disease still lingers at the bedside and in medical literature, though it is transparently false and has been abandoned long since by all contemplative minds.
>
> —S.A.K. Wilson, discoverer of Wilson's disease, as quoted by Reynolds (1)

The concept that certain "mental" syndromes could result from recognizable "physical" disorders or drug use can be traced back to the formal beginnings of Western medicine. Both Greek and Roman physicians observed that agitated mental disorders could be caused by fevers (e.g., the "phrenitis" of Hippocrates) or drugs (e.g., the "delirium due to alcohol or drugs" of Aretaeus) (2–4). The modern etiologic distinction between organic (physical) and functional (psychological) did not, however, enter psychiatric theorizing until the late seventeenth century, with the widespread acceptance of the Cartesian mind/body duality (4). The subsequent popularity of the organic/functional dichotomy reflected the two great divergent trends in psychiatry during the later part of the nineteenth century: 1) the newly emerging "brain psychiatry" fueled by the dramatic increase in knowledge of the anatomy and pathology of the human CNS and 2) an increasing interest and emphasis on mental phenomena and the unconscious in the etiology of mental illness, as exemplified by the work of Pierre Janet and, later, Freud (5, 6).

In contemporary classifications of mental disorders, such as the various editions of the APA's *Diagnostic and Statistical Manual of Mental Disorders,* the concept of "organic" has become more restricted, since there is no *overt* implication that the "nonorganic" disorders are functional or solely caused by psychological factors. The organic/nonorganic distinction is now used merely to separate mental (psychiatric) disorders that are due to an identifiable or presumed "physical" disorder (e.g., stroke, tumor) or to the effects of a psychoactive substance from mental disorders without such identifiable etiologies. These current nosologic distinctions have important prognostic and treatment implications, because they direct the clinician treating a patient with an organic mental disorder to pay special attention to the management (or detection, if the underlying disorder is unknown) of the underlying "physical" disorder or substance-induced condition.

We acknowledge the continued utility of identifying mental disorders caused by a "physical" disorder or substance abuse. The term "organic," however, is plagued by serious and, we believe, intractable connotative problems that have been noted previously (7). The connotative meaning of the term "organic" always returns to its historical roots, which imply a functional/structural, psychological/biological, and mind/body dualism that differs from the clinically useful nosologic distinctions we have just noted. These original dichotomies may have been valuable when we had little understanding of how the CNS functions, but they are at variance with the growing body of evidence of the importance of biological factors in the etiology of the major "nonorganic" mental disorders. Furthermore, the inevitable discomfort of labeling disorders such as schizophrenia and bipolar disorder as "nonorganic" leaves the clinician or researcher with no satisfactory alternative term for the antonym of "organic mental disorders." Finally, the organic/nonorganic distinction encourages the continued stigmatization of the mentally ill by suggesting that such "nonorganic" illnesses as schizophrenia and bipolar disorder are not true medical disorders. The term thus undermines recent efforts to educate the public as well as fellow physicians about our current understanding of mental disorders.

## THE PROPOSAL

As part of the development of *DSM-IV,* a proposal has been made for eliminating the term "organic" and for reorganizing the classification of the organic mental disorders (8). This proposal appears in the *DSM-IV Options Book* (9). In this proposal, disorders previously referred to as "organic mental disorders" would be renamed as either "secondary disorders," if they are due to medical disorders that are classified outside the mental disorders section of the *International Classification of Diseases (ICD)* (e.g., brain tumor, vascular disease, metabolic disturbance), or "substance-induced disorders" (e.g., cocaine intoxication delusional disorder).

In *DSM-III* and *DSM-III-R* the medical disorders classified outside the mental disorders section of the *ICD* were referred to, as is customary, as "physical disorders." Like the term "organic disorders," the term "physical disorders" has connotative problems. Thus, in the remainder of this article, and in *DSM-IV,* the precise if somewhat clumsy term "nonpsychiatric medical disorders" will be used. Thus, as already implicit in the *DSM-II, DSM-III,* and *DSM-III-R* classifications, all psychiatric (mental) disorders are conceptualized as a subset of the larger class of medical disorders.

One of the advantages of this proposal to eliminate the term "organic mental disorders" is that the disorders that previously were awkwardly referred to as "nonorganic" can now be called "primary mental disorders." This results in a clinically useful trichotomy that should facilitate communication about differential diagnosis, as in asking the question, Is this manic behavior *substance-induced, secondary* to a nonpsychiatric disorder, or *primary*?

In order to allow the clinician to indicate the specific etiology of a secondary disorder, the proposal instructs the clinician to include the name of the etiologic "physical" disorder, with both disorders coded on axis I. For example, what would be coded according to *DSM-III-R* as organic mood disorder on axis I and hypothyroidism on axis III would, according to this proposal, be coded as secondary mood disorder due to hypothyroidism on axis I (with a code number for each of the disorders).

One of the important organizing principles of *DSM-III* and *DSM-III-R* is the placement of disorders into major diagnostic groups that share phenomenologic features, so as to facilitate differential diagnosis. For example, in determining the diagnosis of a patient whose predominant symptoms involve a disturbance of mood, it is useful to group together disorders that, by definition, require a disturbance in mood. Therefore, in *DSM-III-R,* bipolar disorder, major depression, cyclothymia, and dysthymia are grouped together under the heading Mood Disorders. However, by having a separate class of organic mental disorders in *DSM-III* and *DSM-III-R,* disorders that are often critical in the differential diagnosis of the presenting disturbance are listed separately. Thus, organic mood disorder and substance-induced mood disorders are listed apart from the listing of the (primary) mood disorders. It is easy for the clinician looking at the *DSM-III* or *DSM-III-R* list of mood disorders to overlook the need to consider organic mood disorder and substance-induced mood disorders as well.

Another important aspect of the proposal addresses this problem by reorganizing the entire classification of mental disorders to distribute the secondary and substance-induced disorders into the major groups with which they share phenomenology. Each major group, such as the anxiety disorders, would begin with the primary disorders (e.g., panic disorder) followed by the secondary disorder (e.g., secondary anxiety disorder) followed by the substance-induced disorder (e.g., substance-induced anxiety disorder). The final category in each major group would be "not otherwise specified," to be used for those frequent instances in which the clinician (using our recommended terminology) is unable to make a judgment about whether the disturbance is secondary, substance-induced, or primary.

Following this principle for organizing major diagnostic groups on the basis of shared phenomenology, the proposal would group together delirium, dementia, and amnestic disorder under the rubric of "cognitive impairment disorders." This has the effect of listing all causes of these syndromes in the same section of the classification. This is in contrast to *DSM-III-R,* where, for example, the seven disorders associated with delirium are listed in three different sections of the classification (dementias arising in the senium and presenium, psychoactive substance-induced organic mental disorders, and organic disorders associated with axis III physical disorders).

Another way to facilitate differential diagnosis is to consider adding to the *DSM-IV* classification additional well-recognized drug-induced and secondary disorders that are not included in the *DSM-III-R* classification. Examples include drug-induced sexual disorders (e.g., cocaine-induced erectile dysfunction), secondary dissociative disorders (e.g., dissociative disorder due to epilepsy), and secondary catatonic disorder (e.g., catatonic disorder due to brain tumor).

## CRITICISMS OF THE PROPOSAL

There have been several criticisms of this proposal. Lipowski (10–12) has argued that the term "organic," properly defined, serves a useful function and that its abolition will create confusion, be at odds with *ICD-10,* and impede communication. Significantly, his definition of "organic" is in complete agreement with our definition of "secondary." Where we disagree is that we believe, as we have noted, that there is no way to avoid the incorrect connotations of the original historical meaning of the term "organic," which will always be a source of confusion when this term is used. The proposal for *DSM-IV* does deviate from *ICD-10* in both terminology and the organization of the classification. However, the constructs and codes of *DSM-IV* substance-induced and secondary disorders would be identical to the *ICD-10* constructs of substance-induced and organic mental disorders, ensuring that all cases would be classified in an equivalent way. Therefore, there should be no problem in ensuring compatibility between the two systems.

Several problems have been noted with the term "secondary." One problem is that the term has been used in psychiatry with a different meaning—to indicate that a mood disorder has temporally followed a nonmood disorder (13). However, this use of the term was primarily a research strategy for achieving maximum homogeneity in research samples and never received widespread clinical use. It has also been noted that intuitively, the term "secondary" should include disorders due to substance use. However, this leads to very cumbersome terminology when one is referring to disorders that are not primary but also not substance-induced; what we propose to call simply "secondary mood disorder" would have to be called something like "mood disorder due to a nonpsychiatric medical disorder." Another criticism is that the use of "secondary" in this context is imprecise, since, ultimately, one could argue that all disorders are secondary to some underlying process. However, applying the term "secondary" to all disorders would obscure what we have noted to be a useful treatment-relevant distinction within the classification of mental disorders. Finally, it has been argued that the term "secondary disorder" will be unfamiliar to nonpsychiatric physicians who are used to the term "organic." However, this objection overlooks the way in which the term will actually be used, as in "I think the problem is a secondary mood disorder due to hypothyroidism." When "secondary" is used in context, the nonpsychiatric physician will have no trouble understanding exactly what is meant by the term.

The term "secondary" became our final choice for the proposal only after we concluded that alternative terms were even less satisfactory. In our original proposal we had suggested the term "symptomatic," which had been used in this country with a similar meaning. The term even now has current usage in European psychiatry and is part of the chapter heading for the organic section of the mental disorders chapter of *ICD-10.* This term was ultimately rejected when we realized that in communications with our nonpsychiatric colleagues the term would be extremely confusing. (Consider the following exchange. Psychiatrist: "Thank you for referring Mr. Jones. I believe he suffers from a symptomatic mood disorder." Internist: "I don't understand what you are talking about. I know he is symptomatic—that's why I sent him to you.")

Because of the problems identified with finding a substitute for the term "organic," it has been suggested that the solution is to have no term at all, but merely to note, in the name of the disorder, the etiologic nonpsychiatric disorder, such as "depressive disorder due to hypothyroidism." However, in the absence of a generic term, such as "secondary depressive disorder," discussions of differential diagnosis would have to use very cumbersome language, for example, "Rule out a depressive disorder due to a nonpsychiatric medical disorder" (instead of simply "Rule out a secondary depressive disorder"). Furthermore, not having a generic term would preclude the availability of simple terminology for what we believe is a clinically useful conceptual trichotomy of all mental disorders as primary, secondary, or substance-induced.

Removing the term "organic mental disorders" from the classification may be viewed as radical. However, from another perspective these proposals for changes in terminology and reorganization of the entire classification are conservative, since they continue the traditional nosologic dichotomy between (to use the new terminology) primary mental disorders and those that are either substance-induced or secondary to a nonpsychiatric medical disorder. Fogel (14) has argued, using as an example the *DSM-III-R* distinction between major depression and organic mood disorder, that the reliability and validity of psychiatric diagnosis would be improved by keeping axis I strictly phenomenologic and identifying relevant organic factors on axis III. Organic factors judged to be causal or contributory to an axis I disorder could be indicated by a defined symbol, as discussed in Williams's 1985 review of critiques of the *DSM-III* multiaxial system (15, 16). Thus, Fogel argues that the current proposal would perpetuate what is now an unreliable and invalid nosologic distinction.

Fogel's suggestion of a purely descriptive axis I nosology may, at first glance, seem appealing. However, there are several problems with this suggestion. First, it is incompatible with the proposed *ICD-10* classification, which has largely adopted the *DSM-III-R* approach by including such categories as organic affective disorder, organic anxiety disorder, and organic personality disorder. Fogel's proposal would therefore significantly disrupt compatibility between *DSM-IV* and *ICD-10*. More important, if his proposal were systematically applied to other disorders, for example, schizophrenia, the same diagnostic term, perhaps "schizophrenic syndrome," would be applied to patients with schizophrenia-like symptoms regardless of whether drugs or nonpsychiatric medical disorders were judged to be the cause. Admittedly, the clinical judgment about the etiologic role of "organic" factors is often extremely difficult and sometimes impossible, but eliminating this treatment-relevant distinction from our nosology and relegating it to an axis III symbol hardly seems to represent an advance.

The term "cognitive impairment disorders" has been criticized on the grounds that cognitive impairment is frequently a prominent feature of other disorders, such as schizophrenia and major depression, and therefore it is misleading to single out delirium, dementia, and amnestic disorder as cognitive impairment disorders. However, cognitive impairment is, in fact, the defining feature of these three disorders, whereas it is not invariably present in any other mental disorders. (The exception to this is mental retardation, which by tradition, has always been classified outside the organic mental disorders.) In a similar fashion, mood disturbance is frequently a prominent feature of disorders that are not classified as mood disorders, such as schizophrenia, but it is the defining feature of all of the mood disorders.

The part of the proposal that would distribute the secondary and substance-induced disorders into the major diagnostic groups with which they share phenomenology has been criticized on two grounds. First, it is argued that if this is done, the unitary concept of "secondary" and "substance-induced" will be lost. Second, not having a single section for these disorders would make the classification less convenient for clinicians who focus primarily on the treatment of mental disorders in medical and substance abuse settings. We believe that these objections can be met by including appendices that list all of the secondary and all of the substance-induced disorders together.

## CONCLUSIONS

The organic/nonorganic distinction arose historically from the philosophical controversy about the relation between mind and brain, which continues to generate controversy in our field (17). The proposal we have outlined in no way solves this apparently intractable problem. However, we would argue that it provides a terminology that avoids a now outmoded conceptualization of the issues. Similarly, the historical distinction between psychiatric and nonpsychiatric disorders arose largely on the basis of practical considerations about which disorders were managed by which kinds of clinicians. While this distinction continues to have practical utility, the proposal does not help clarify the inherently difficult boundary between these two types of disorders or the related problem of defining mental (psychiatric) disorder itself (18).

Any change in terminology or the organization of the classification of mental disorders is a potential source of disruption for both researchers and clinicians. However, the potential benefits of this proposal for clarity and for facilitating differential diagnosis justify putting to rest the familiar but now anachronistic term "organic mental disorders."

# Magnetic Resonance Imaging of the Posterior Fossa in Autistic Adults

**H. Jordan Garber, M.D., and Edward R. Ritvo, M.D.**

*Magnetic resonance imaging measurements were obtained for 12 adults with* DSM-III-*defined autism and a matched group of 12 normal subjects. No significant differences were found for mean midsagittal areas of pons, fourth ventricle, cerebellar vermis, or vermis lobules. No significant brain abnormalities were observed in either group.*

(Am J Psychiatry 1992; 149:245–247)

Although autistic disorder may result from organic insults (1) or genetic influences (2), brain imaging has not consistently shown structural abnormalities (3). Ventricular enlargement or reversed cortical asymmetry was noted in some autistic subjects by pneumoencephalography and CT but not by all investigators (4, 5), and various cortical abnormalities have been noted by magnetic resonance imaging (MRI) (6) but not in all studies (3). Evidence of abnormal CNS development in the posterior fossa has included 1) lower cerebellar Purkinje cell counts post-mortem (7, 8); 2) smaller midsagittal MRI area of the posterior-superior vermis (lobules VI and VII) in an autistic adult (9) and in 18 autistic subjects (mean age=20.9 years) compared with 12 normal subjects (10); and 3) smaller midsagittal MRI area of the pons (11) and larger fourth ventricle (12) in young autistic subjects (mean age=11.3 years) compared with normal subjects.

Our previous MRI study of 15 young autistic subjects (mean age=11.6 years) and 15 matched normal subjects found few structural abnormalities (3) and no significant differences for areas of the cerebellar vermis lobules (13), fourth ventricle (3), or pons (unpublished data). Because of possible maturational effects and age difference between our previous autistic subjects and those of Courchesne et al. (10), we used MRI to study adult autistic subjects.

## METHOD

The autistic adults were recruited through a university neuropsychiatric institute; they had been previously diagnosed according to *DSM-III* criteria by one of us (E.R.). The autistic subjects had middle to high functioning (14), were medication-free, and had no other medical or neurological illnesses. The normal comparison subjects, recruited by advertisement and personal contact, were of normal or higher intelligence and had no personal or family history of neurological or psychiatric illnesses. After approval from the Human Subjects Protection Committees at the university and after informed consent had been obtained from each subject or guardian, sagittal MRI was performed on 12 autistic subjects 18–38 years old (mean age=27.2 years, SD=5.3) and 12 normal volunteers 21–35 years old (mean age=26.4 years, SD=3.6). The groups did not differ by age ($t=0.407$, $df=22$, $p<0.69$) or sex distribution (three of the autistic subjects were women and nine were men; four of the normal subjects were women and eight were men).

Sagittal images were obtained at 1.5 T (Picker Vista MR, $T_1$-weighted sequence: repetition time=800 msec, time to echo=26 msec, two signals averaged, 256-gra-

**TABLE 1. Measurements From Magnetic Resonance Imaging of 12 Adult Autistic Subjects and 12 Normal Subjects**

| | Autistic Subjects | | Normal Subjects | | Analysis | |
|---|---|---|---|---|---|---|
| Midsagittal Measurement | Mean | SD | Mean | SD | t (df=22) | p |
| Area | | | | | | |
| Cerebrum (cm$^2$) | 89.15 | 7.59 | 87.92 | 8.37 | 0.376 | <0.71 |
| Pons (cm$^2$) | 5.69 | 0.61 | 5.75 | 0.58 | 0.237 | <0.81 |
| Fourth ventricle (cm$^2$) | 1.10 | 0.22 | 0.96 | 0.22 | 1.697 | <0.10 |
| Cerebellar vermis | | | | | | |
| Total (cm$^2$) | 9.52 | 0.76 | 9.35 | 0.90 | 0.507 | <0.62 |
| Ratio of vermis to cerebrum | 0.11 | 0.01 | 0.11 | 0.02 | 0.024 | <0.98 |
| Lobules I–V (cm$^2$) | 4.63 | 0.51 | 4.48 | 0.40 | 0.803 | <0.43 |
| Lobules VI–VII (cm$^2$) | 3.15 | 0.43 | 2.99 | 0.41 | 0.969 | <0.34 |
| Ratio of lobules VI–VII to I–V | 0.69 | 0.14 | 0.67 | 0.08 | 0.527 | <0.60 |
| Volume of fourth ventricle (cm$^3$) | 1.11 | 0.15 | 0.99 | 0.20 | 1.670 | <0.11 |

dient steps, interleaved multislice technique, 12 contiguous slices, 5-mm thick). Midsagittal slices were positioned in a standardized manner from the coronal pilot scan of each subject as described elsewhere (3); the sagittal image grid was centered on the third ventricle and apex of the fourth ventricle. Results were evaluated by two MRI radiologists who were blind to diagnosis.

Areas were measured by two independent and blind raters using computerized planimetry functions of the MRI console (magnified four times, consistent windows and levels). Pontine boundaries were defined as described by Gaffney et al. (11); fourth ventricle measurements were made as we reported elsewhere in detail (3); boundaries within the cerebellar vermis were defined as described by Courchesne et al. (10). Total vermis area measurement used a caudal boundary defined by a line joining the apex of the fourth ventricle to the posterolateral fissure, to include lobules VIII (pyramis) and IX (uvula) but to exclude nodulus. Total cerebral area was measured on the midsagittal slice.

Measurements were made twice by each rater, and the four values were averaged. Values had intraclass correlations greater than 0.92 (intrarater) and greater than 0.91 (interrater) for all measures. Student's t tests (two-tailed) were used for between-group comparisons, and Pearson correlation coefficients were used to explore within-group relationships of measurements with age.

## RESULTS

Radiologic evaluation of all sagittal images revealed no significant focal abnormalities in either the autistic group or the normal comparison group. Enlargement of the lateral ventricles was noted in one autistic subject and one normal subject, but no abnormalities were apparent in the posterior fossa of any of our subjects.

Results of morphologic measurements are given in table 1. There were no differences between groups for midsagittal measures of the pons, fourth ventricle, vermis, or vermis lobules. Area ratios of total vermis to cerebrum and of lobules VI–VII to lobules I–V did not differ between groups. Correlations of age were significant only for increasing age with greater pontine area ($r=0.60$, $N=12$, $p<0.04$) and fourth ventricle volume ($r=0.62$, $N=12$, $p<0.03$) in normal subjects but not in autistic subjects (pons: $r=0.18$, $N=12$, $p<0.58$; fourth ventricle volume: $r=0.18$, $N=12$, $p<0.58$). Between-group differences for age correlations were not statistically significant.

## DISCUSSION

Consistent with our previous study of younger autistic subjects (3, 13), we found no focal abnormalities and no measurable differences in the posterior fossa of autistic adults compared with normal subjects. Although Courchesne et al. (9, 10) noted vermal hypoplasia as a significant finding in some autistic subjects, we have not observed this in any autistic subject. However, we excluded autistic subjects with low functioning or any "organic history," and radiologic evaluations were limited to sagittal images. Since Gaffney and Tsai (6) noted MRI abnormalities in six of 14 autistic subjects, three of whom had substantial medical histories or evidence of neurological disease, MRI may be revealing when there is a high index of suspicion for specific CNS abnormalities. Nonetheless, our results do not confirm previous findings of abnormal pontine (11), cerebellar (10), or fourth ventricle (12) areas in autistic disorder.

We incorporated several methodological improvements in this study: 1) our comparison group was selected specifically as normal subjects for autism research (previous investigators used "radiologic control" cases from MRI files [10–12]); 2) we used one MRI protocol with consistent midsagittal slice positioning (Courchesne et al. [10] and Gaffney et al. [6, 11, 12] used varying MRI methods within groups, and neither defined the midsagittal position); and 3) we obtained contiguous 5-mm thick slices (Gaffney et al. [6, 11, 12] used 1-cm thick slices and Courchesne et al. [10] left gaps between slices, both of which may have affected accuracy). Our measurements had high reproducibility and reliability, yielding a normal ratio for vermis to cerebrum similar to previously reported values of 0.09 (16) and 0.11 (3).

We found significant age correlations with pontine area and fourth ventricle volume in normal subjects but not in autistic adults. Gaffney et al. (11) also found that age correlated with pontine area in normal subjects and not in autistic subjects but did not evaluate age effects on the fourth ventricle (12). Although the difference in correlations between our groups was not statistically significant, the small size of these groups may have obscured differences by type II errors. Larger groups and longitudinal studies are needed to further evaluate maturational effects on the posterior fossa in autism.

# High-Intensity Signals in Alzheimer's Disease Without Cerebrovascular Risk Factors: A Magnetic Resonance Imaging Evaluation

**Anand Kumar, M.D., David Yousem, M.D., Elaine Souder, Ph.D., R.N., David Miller, M.D., Gary Gottlieb, M.D., Raquel Gur, M.D., Ph.D., and Abass Alavi, M.D.**

---

*The authors examined the relationship between Alzheimer's disease, without cerebrovascular risk factors, and high-intensity signals on magnetic resonance imaging (MRI) with a 1.5-tesla scanner. There were no significant differences in MRI high-intensity signals between subjects with Alzheimer's disease (N=16) and healthy control subjects (N=23).*

(Am J Psychiatry 1992; 149:248–250)

---

Alzheimer's disease is the most common cause of dementia in the Western hemisphere, and several technologically advanced imaging modalities including magnetic resonance imaging (MRI) have been used to study Alzheimer's disease (1, 2). The unprecedented sensitivity of MRI to brain pathology and its increasing use have led to a plethora of reports purporting to show structural abnormalities across a broad spectrum of neuropsychiatric conditions including Alzheimer's disease (3, 4).

High-intensity signal abnormalities on MRI—regions that appear bright on $T_2$-weighted and proton density images—have received considerable attention (1, 3). They are located primarily in the periventricular white matter, deep white matter, and subcortical regions of the brain. While the precise etiology of these signals remains unclear, it appears likely that several factors including ischemic changes, increased water content of brain tissue, and demyelination may be responsible for their presence (3). They have been reported in several conditions including normal aging, multiple sclerosis, hydrocephalus, multi-infarct dementia, and affective disorders (3, 4). There are conflicting reports regarding the presence of MRI high-intensity signals in Alzheimer's disease and the role of associated vascular risk factors in their development (1, 2, 5).

This study was designed to clarify the relationship between periventricular and deep white matter high-intensity MRI signals and Alzheimer's disease unassociated with major cerebrovascular risk factors. In addition, we sought to examine certain subcortical gray nuclei—caudate, lenticular nuclei, and thalamus—in Alzheimer's disease for the presence of high-intensity signals and to compare these to signal changes in healthy, age-matched control subjects.

## METHOD

The study groups consisted of 16 subjects with probable Alzheimer's disease (eight women, eight men; mean age=67 years, SD=8) and 23 healthy, age-matched control subjects (12 women, 11 men; mean age=68 years, SD=8). The Alzheimer's disease subjects met the criteria for probable Alzheimer's disease of the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (6) and were free of major vascular risk factors such as hypertension, strokes, transient ischemic attacks, and diabetes. All Alzheimer's disease subjects, with the exception of two, had Mini-Mental State examination scores (7) greater than 16 (mean=23, SD=5). Two Alzheimer's disease subjects had Mini-Mental State examination scores of 12 each. The control subjects were screened according to the same health criteria as the Alzheimer's disease subjects and were also free of significant neurological, psychiatric, and systemic disease; head injury; and major vascular risk factors such as hypertension, transient ischemic attacks, and diabetes. In addition, both Alzheimer's disease and control subjects had normal laboratory indices, i.e., complete and differential blood counts; he-

patic, renal, and thyroid panels; $B_{12}$ and folate levels; and syphilis serology.

The MRI studies were performed with a 1.5-tesla General Electric Signa scanner (Milwaukee, Wis.) and with a quadrature head coil. Scans included sagittal short repetition time and axial long repetition time series with 5-mm contiguous slices. Only the transaxial $T_2$-weighted and proton density images (repetition time=3000 msec, echo times=30 and 80 msec) were examined by a qualified neuroradiologist (D.Y.) for evaluation of periventricular white matter high-intensity signals, deep white matter high-intensity signals, and subcortical gray nuclei high-intensity signals. The neuroradiologist was blind to the clinical status of all subjects.

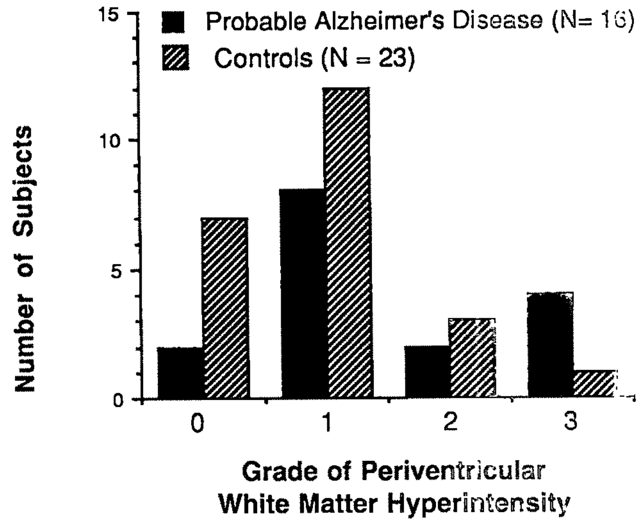
Periventricular high-intensity signals were rated by the neuroradiologist on a 0–3 scale of severity (1) (0=absent, 1=frontal or occipital caps or pencil-thin lining of the lateral ventricle, 2=smooth halo around the lateral ventricle, 3=irregular periventricular high-intensity signals extending into the deep white matter). Deep white matter high intensities were also graded on a scale of 0–3 (1) (0=absent, 1=punctate foci, 2=early confluence of foci, 3=large confluence of foci). High-intensity signals in the caudate and lenticular nuclei and thalami were rated as follows: 0=absent, 1=punctate, 2=multipunctate, 3=diffuse (4).

The robust rank-order test was used to examine differences in ratings between the Alzheimer's disease and control groups in periventricular white matter high-intensity signals, deep white matter high-intensity signals, and subcortical gray nuclei high-intensity signals. Within both groups the Spearman rank-order correlation coefficient was used to determine whether there was any association among serum cholesterol and triglyceride levels, Mini-Mental State examination scores; age; and ratings of periventricular, deep white matter, and subcortical high-intensity signals.

## RESULTS

In our study groups, 37% (N=6) of the Alzheimer's disease subjects and 17% (N=4) of the control subjects had periventricular white matter high intensity of grade 2 or greater. The exact number of Alzheimer's disease and control subjects who fell into specific periventricular white matter high-intensity severity groups is displayed in figure 1. Nineteen percent (N=3) of Alzheimer's disease subjects and 9% (N=2) of control subjects presented with deep white matter high intensity of grade 2 or greater. Regarding subcortical high-intensity signals, none of the Alzheimer's disease subjects and 9% of the control subjects had subcortical gray nuclei high-intensity signal changes of grade 2 or greater. The differences between the Alzheimer's disease and control groups on all three measures were statistically insignificant (robust rank-order test). Using the Spearman rank-order correlation test (after correcting for ties), we found that within the Alzheimer's disease group there were positive correlations between age and both periventricular white matter high intensity ($r_s$=0.5, df=14, $p<0.01$) and deep white matter high intensity ($r_s$=0.55, df=14, $p<0.01$) and between subcortical gray nuclei and Mini-Mental State examination scores ($r_s$=0.59, df=14, $p<0.01$). The control group demonstrated a significant inverse correlation between serum triglyceride levels and subcortical gray nuclei high-intensity signals ($r_s$=−0.46, df=21, $p<0.05$).

**FIGURE 1. Severity of Periventricular White Matter High-Intensity Signals in Subjects With Probable Alzheimer's Disease and Healthy Control Subjects**



## DISCUSSION

These data demonstrate that in our study groups, in the absence of major vascular risk factors such as hypertension, diabetes, and cerebral ischemic events, the Alzheimer's disease group was not associated with a statistically significant higher prevalence of high-intensity signals than was the healthy, age-matched control group. Compared with the control group, the Alzheimer's disease group did, however, have twice the prevalence of periventricular high-intensity signals. In addition, within the Alzheimer's disease group both periventricular white matter high intensity and deep white matter high intensity increased significantly with age, while subcortical gray nuclei high-intensity signals showed a significant inverse correlation with severity of dementia, as measured by the Mini-Mental State examination. The prevalence of MRI high-intensity signals in the healthy elderly control group was low and consistent with other reports that demonstrated a low prevalence of high-intensity signals in healthy subjects (5). The inverse correlations between subcortical gray nuclei and triglyceride levels in control subjects and between subcortical gray nuclei high-intensity signals and clinical severity in Alzheimer's disease subjects are counterintuitive and do not have any obvious explanation.

MRI high-intensity signals have been reported across a broad spectrum of clinical conditions (3, 4). While there are conflicting reports regarding the presence of high-intensity signals in Alzheimer's disease (1, 5, 8), several fundamental clinical and methodological factors may explain the apparent discrepancies among studies. Earlier reports demonstrating a higher prevalence of periventricular white matter high-intensity signals in Alzheimer's disease combined subjects with probable/possible Alzheimer's disease in their samples or combined Alzheimer's disease subjects and subjects with vascular dementia (1, 2, 8). In addition, the probable Alzheimer's disease group included subjects with essential hypertension—a major cerebrovascular risk factor that has consistently been shown to be associated with MRI high-intensity signals (1, 9). It should be pointed out that the presence of hypertension per se does not preclude a diagnosis of probable Alzheimer's disease based on the criteria of the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (6). However, in order to determine whether high-intensity signals on MRI are associated with the pathophysiology of Alzheimer's disease, it is necessary to restrict the study sample to carefully screened Alzheimer's disease subjects who are free of confounding risk factors.

Our finding of a low prevalence of MRI high-intensity signals in a healthy elderly control group that was free of significant vascular risk factors corroborates earlier reports on MRI high-intensity signals in healthy elderly subjects (5, 9). In elderly subjects the presence of MRI high-intensity signals correlates significantly with age and vascular risk factors, especially hypertension and cerebral ischemia (9). The prevalence of high-intensity signals has also been shown to be high in subjects with stroke and vascular dementia (5, 10). Collectively, these findings indicate that overt and subclinical vascular disease is largely responsible for the signals often observed in the elderly.

The pathophysiological factors responsible for high-intensity signals may vary across clinical conditions. In healthy elderly subjects the low myelin content of axons around the frontal horns, loss of ventricular ependymal lining, and the convergence of interstitial fluid to the frontal horns may contribute significantly to the signals on MRI (3). Ischemic changes, the dilation of perivascular spaces, and vascular ectasia are considered responsible for the signals in vascular dementia and strokes (10). In multiple sclerosis, subependymal demyelination is believed to be the explanation for the signals seen (3). Thus there is compelling evidence to suggest that high-intensity signals are nonspecific in etiology and that a variety of pathophysiological mechanisms, both vascular and otherwise, can produce the same appearance on MRI.

These data establish that in our study group of probable Alzheimer's disease subjects who were free of major vascular risk factors, the prevalence of MRI high-intensity signals was low and not significantly different from that of healthy control subjects. The prevalence of periventricular white matter high-intensity signals was greater, albeit statistically insignificant, in the Alzheimer's disease group than in the control group. It is possible that the relatively small size of our study groups precludes the higher prevalence of periventricular white matter high intensity in the Alzheimer's disease group from becoming statistically significant. In addition, our current study group was restricted to subjects with mild to moderate dementia. It is therefore possible that severe Alzheimer's disease may be associated with a higher prevalence of high-intensity signals on MRI. Future studies aimed at further clarification of this question should extend the study to well-characterized Alzheimer's disease subjects with severe cognitive impairment. Special attention should continue to be paid to screening out confounding conditions and risk factors that limit interpretation of data.

# Glutamate and Other CSF Amino Acids in Alzheimer's Disease

Nunzio Pomara, M.D., Rajkumar Singh, M.D., Dennis Deptula, Ph.D., James C.-Y. Chou, M.D., Miriam Banay Schwartz, Ph.D., and Peter A. LeWitt, M.D.

*The authors compared CSF amino acid levels of 10 patients with mild to moderate dementia and probable Alzheimer's disease who had never received antidepressant or neuroleptic medication with those of 10 normal subjects of similar age. The Alzheimer's patients had significantly higher levels of CSF glutamate. This finding was not related to age, sex, or severity of dementia. Elevated CSF glutamate may reflect greater glutamatergic activity early in the course of Alzheimer's disease. The authors speculate that the excitotoxic effects of glutamate may contribute to progressive neuronal loss in Alzheimer's disease.*

(Am J Psychiatry 1992; 149:251–254)

Numerous neurotransmitters, including acetylcholine, norepinephrine, serotonin, somatostatin, and corticotropin-releasing factor (CRF), have been clearly implicated in Alzheimer's disease, but there is a growing body of evidence suggesting that excitatory amino acids, particularly glutamate, may also have an important role in this disease. Excitatory amino acid neurotransmitters such as glutamate and aspartate are known to have neurotoxic (excitotoxic) effects that have been implicated in stroke, head trauma, and seizure disorders. More recently, there has been considerable interest in excitatory amino acid theories of neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease (1).

Animal experiments have suggested that excitatory amino acid neurotransmitter systems—specifically the N-methyl-D-aspartate (NMDA) receptor, a type of glutamate receptor—are important in learning and memory. As reviewed by Greenamyre and Young (2), NMDA antagonists have been shown to prevent spatial discrimination learning. Furthermore, it has been hypothesized that NMDA receptor stimulation may be necessary for new learning. Given the possible role of excitatory amino acid neurotransmitter systems in memory and learning as well as reports of lower levels of brain glutamate levels (3–5) and less glutamate receptor density (especially the NMDA receptor) (6–8) in Alzheimer's disease, it is reasonable to hypothesize that alterations in glutamatergic activity may play a role in both the clinical features and the pathophysiology of Alzheimer's disease (2, 9). Koh et al. (10) have recently found that beta-amyloid, a protein that is widely present in the brain of subjects with Alzheimer's disease, can increase susceptibility to excitotoxic agents such as glutamate.

Several post-mortem studies have compared brain glutamate levels in Alzheimer's disease to those in control subjects. Although Tarbit et al. (11) reported no difference in the hippocampus, other investigators (3–5) have found lower levels of glutamate in the frontal cortex and the temporal cortex of Alzheimer's patients than in control subjects. These findings of lower glutamate concentrations in the cortexes of presumably severely impaired patients with Alzheimer's disease are consistent with a decrease in glutamatergic activity in end-stage Alzheimer's disease.

Glutamate has also been studied in vivo in Alzheimer's disease. Procter et al. (4) measured antemortem levels in biopsy specimens and found that glutamate was significantly reduced in the temporal cortex but not in the frontal cortex of patients with Alzheimer's disease. The reduction in glutamate in the temporal cortex of these antemortem biopsy specimens was smaller than that found in a post-mortem sample, which presumably represented later stages of Alzheimer's disease (4). This may suggest that decreasing brain glutamate levels parallel disease progression.

Studies of CSF provide another method of examining progressively degenerative diseases such as Alzheimer's during early stages. In an attempt to evaluate possible alterations in excitatory amino acids before the end stage of the illness, several investigators have examined excitatory amino acids in the CSF of patients with Alzheimer's disease. Three CSF studies found no significant difference between patients with Alzheimer's disease and control subjects (4, 12, 13). Unfortunately, these studies had one or more methodological limita-

[b] Values for only nine patients with Alzheimer's disease were available; df=17.

tions, including 1) use of patients with a history of receiving psychotropic medication, 2) use of young control subjects or control subjects with other neurological disorders, and 3) inclusion of subjects with Alzheimer's disease whose degree of dementia was not specified. In the current study, we measured CSF concentrations of free glutamate and other amino acids in patients with probable Alzheimer's disease who had mild to moderate dementia and who had never received psychotropic drugs. These CSF amino acid levels were compared to those of subjects of similar age.

## METHOD

The 10 subjects with dementia—four men and six women—had a mean age of 59.7 years (SD=10.8) and met the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders criteria for probable Alzheimer's disease as well as the *DSM-III* criteria for primary degenerative dementia. These patients were compared with 10 subjects—four men and six women—of similar age; their mean age was 63.8 years (SD=11.2). Patients were mildly to moderately demented (mean Global Deterioration Scale [14] score=4.7, SD=0.4; mean WAIS-R [15] score=79.4, SD=10.9; mean Mini-Mental State examination [16] score=16.6, SD=3.9) and were being cared for by their families at home. The mean duration of illness as reported by caregivers was 5.4 years (SD=4.7). Comparison subjects were free of medical and psychiatric illness. None of the participants had a history of treatment with neuroleptics or antidepressants. All patients and comparison subjects consented to participation in the study after its nature had been explained to them.

Lumbar punctures were performed with patients in the lateral decubitus position between 8:00 and 9:00 a.m. following overnight bed rest and fasting. Approximately 20 cc of CSF was collected on ice in a standardized manner and immediately frozen at –70 °C. Aliquots from a pooled specimen of the 3rd–17th ml were used for determination of free amino acids by using precolumn derivatization with 1-naphthylisocyanate and separation with reverse high performance liquid chromatography on a C18 silica column (17).

## RESULTS

As shown in table 1, the mean CSF concentration of free glutamate was significantly higher in patients with Alzheimer's disease than in comparison subjects. The mean CSF proline level of the patients was also significantly higher than that of the comparison subjects. Although the mean CSF aspartate level was not significantly higher in patients with Alzheimer's disease, CSF aspartate correlated strongly with glutamate ($r=0.83$, $N=10$, $p<0.001$). In contrast to findings of higher levels of glutamate and proline, patients with Alzheimer's disease had lower mean CSF concentrations of taurine, ornithine, and lysine than the comparison group.

Pearson correlations revealed no significant relationship between glutamate concentrations and severity of dementia as measured by the Global Deterioration Scale and the Mini-Mental State examination. However, it should be noted that the range of severity in our patients was somewhat constricted in that all patients had a Global Deterioration Scale score of 4 or 5. No significant relationships were found between CSF glutamate concentration and age, gender, or duration of illness.

## DISCUSSION

Excitatory amino acids in general and glutamate in particular have been hypothesized to contribute to a neurotoxic process involved in the pathogenesis of Alzheimer's disease (9). Although not consistently found in all reports, glutamate and its receptors have been observed to be lower than normal in post-mortem studies of patients with Alzheimer's disease. Although previous CSF studies have not demonstrated a difference in CSF glutamate levels between subjects with Alzheimer's disease and control subjects (4, 12, 13), Smith et al. (12) did find a significant positive correlation between CSF glutamate levels (which were not different from those of control subjects) and cognitive impairment in Alzheimer's disease.

There are methodological limitations, however, to the existing CSF studies. These include use of control subjects with neurological disorders (4, 12), use of young or not age-matched control subjects (12, 13), and failure to specify drug status or maintain all subjects drug free (4, 13). Procter et al. (4) and Smith et al. (12) used patients with neurological disorders as control subjects, and these disorders themselves could affect CSF levels of glutamate or other amino acids. The subjects with Alzheimer's disease in the reports by Procter et al. (4) and Degrell et al. (13) were not all kept drug free. This is an important shortcoming because neuroleptics antagonize the effects of dopamine, which is known to modulate glutamate release (18). The effects of neuroleptics on CSF glutamate levels may have masked any differences between groups. Although Smith et al. (12) did keep their subjects with Alzheimer's disease drug free for 1 week, this is a relatively brief period for complete washout of neuroleptic effects.

The precise relationship between glutamate and the severity of Alzheimer's disease remains unclear. Although most studies reported lower brain glutamate levels, the subjects in these reports were generally in the later stages of the disease. Unfortunately, Smith et al. (12) and Procter et al. (4) did not report the severity or duration of illness in their subjects with Alzheimer's disease in adequate detail. However, Degrell et al. (13) found a trend ($p<0.10$) for CSF glutamate levels to be negatively associated with age in a group of senile subjects with Alzheimer's disease. To the extent that severity of Alzheimer's disease parallels increasing age, this supports a theory of progressive loss of glutamatergic activity in Alzheimer's disease and is consistent with the glutamate hypothesis of Alzheimer's disease proposed by Maragos et al. (9). Unfortunately, the finding of Smith et al. (12) that CSF glutamate in Alzheimer's disease (although not different from control subjects) positively correlated with cognitive impairment is difficult to integrate into this model without more information about severity and duration of illness in those subjects.

Our data are consistent with the glutamate hypothesis of Alzheimer's disease, which suggests that glutamatergic activity is greater in the early stages of the disease. However, a more intriguing question, as yet unanswered, is whether there are glutamatergic abnormalities that precede the onset of clinical symptoms of dementia and that might, in fact, lead to Alzheimer's disease. Although perhaps methodologically difficult, it would be important to study glutamate in a group of normal elderly subjects and follow them longitudinally as some of them developed Alzheimer's disease. This would allow direct exploration of whether glutamate activity is higher in the very early stages of Alzheimer's disease.

It is important to note the limitations of this pilot study. The elevation in glutamate levels was slight and may have been due in part to conversion of glutamine to glutamate during storage of the CSF samples. However, this effect should have occurred in CSF samples from both comparison subjects and patients because samples from both groups were handled identically. Another limitation is the interpretation of changes in CSF glutamate levels as reflecting changes in transmitter glutamate. In fact, only a small portion of brain glutamate is in the transmitter pool, while the majority of brain glutamate is used intracellularly for metabolic processes. CSF glutamate may also originate in the spinal cord. The actual percentage of CSF glutamate that arises from the transmitter pool is unknown and may be small.

In addition to higher glutamate levels, we also observed that CSF taurine levels were lower in Alzheimer's disease. Since taurine is thought to be an inhibitory neuromodulator, lower taurine levels might reflect decreased inhibitory tone, which might facilitate greater glutamatergic activity. We also found that CSF proline levels were higher in patients than in comparison subjects. Although proline, like taurine, is thought to have inhibitory effects, it might also affect glutamate levels because it is a potential substrate for glutamate synthesis (19). Furthermore, proline itself is believed to modulate the NMDA receptor. Levels of ornithine, another potential substrate for glutamate synthesis (19), were also lower in patients than in comparison subjects. The significance of lower CSF lysine levels is unknown.

We were unable to correlate CSF glutamate levels with severity of dementia. However, our study group was small and represented a narrow range of impairment. Without a larger study group demonstrating a wider range of impairment, we cannot adequately test whether glutamate levels decrease as Alzheimer's disease progresses, as suggested by Degrell et al. (13).

To the extent that CSF glutamate levels reflect glutamate neurotransmitter activity, our findings may be due to greater glutamate activity in early Alzheimer's disease and provide support for the glutamate hypothesis of Maragos et al. (9), who stated, "Cell death due to neuronal toxicity could result from excessive synthesis or release of glutamate or a glutamate-like substance, faulty glutamate reuptake, decreased glutamate degradation, or decreased inhibition of excitatory neurons. Any of these aberrant processes could, early in the disease, increase local levels of glutamate and so initiate a slow, progressive degeneration and eventual death of neurons." Our data, derived from a small group of mildly to moderately demented subjects, are consistent with this hypothesis.

# Modified Activity of the Human Auditory Cortex During Auditory Hallucinations

Jari Tiihonen, M.Sc.D., Riitta Hari, M.Sc.D., Hannu Naukkarinen, M.D., Ranan Rimón, M.Sc.D., Veikko Jousmäki, B.Sc., and Matti Kajola, M.Sc.

*Previous reports have shown abnormalities in brain metabolism and evoked responses of schizophrenic patients with hallucinations. The authors recorded electric and magnetic auditory responses during transitory auditory hallucinations in two patients. Small but replicable response delays occurred during hallucinations. The results suggest that the effect of hallucinations on auditory cortex activity is similar to the effect of real sounds.*

(Am J Psychiatry 1992; 149:255–257)

Auditory hallucinations are one of the main symptoms that characterize the acute phase of schizophrenia. In positron emission tomography and single photon emission tomography studies, hallucinations have been associated with increased glucose metabolism in the right hemisphere (1), especially in the hippocampus, parahippocampus, and amygdala (2). Therefore, hallucinations may result from hyperactivity in the limbic area resulting from a lack of normal neocortical inhibition (2). Patients suffering from chronic auditory hallucinations tend to show greater than normal glucose metabolism in the left temporal area (3). Abnormalities in auditory evoked potentials have been observed at the brainstem level (4).

Magnetoencephalography (MEG) is a relatively new noninvasive method based on the detection of cerebral magnetic fields outside the skull (5). Whereas the EEG results from neural currents oriented both radially and tangentially to the skull, MEG is sensitive to tangential currents only, thus mainly reflecting activity of pyramidal cells in the fissural cortex. Magnetic fields are not substantially affected by layers of inhomogeneous electric conductivity, as are the skull and the scalp. Therefore, with MEG it is possible to study cortical brain activity with good spatial and temporal resolution.

Continuous speech and music maskers delivered to one ear dampen and delay the N100m response (magnetic deflection peaking around 100 msec) to stimuli of both ears (6). In the present study we recorded auditory evoked potentials and auditory evoked magnetic fields during hallucinations and normal periods in two patients in order to detect signs of an analogous "internal masking."

## METHOD

### *Subjects*

We studied two cooperative male patients suffering from intense transitory hallucinations. Subject 1 (35 years old) had committed several thefts and robberies but had been found not responsible for his actions for reasons of insanity caused by schizophrenia. Subject 2 (44 years old) fulfilled the *DSM-III-R* criteria for schizophrenia. Both patients had their eyes open during the recordings and indicated with finger movements the beginnings and endings of auditory hallucinations. Long-latency auditory evoked potentials were recorded for subject 1, and auditory evoked magnetic fields were recorded for subject 2.

### *Recordings and Data Analysis*

In the recordings of auditory evoked potentials (subject 1), the stimuli were binaural 50-msec, 800-Hz sine wave tones, 60 dB above the hearing level, delivered once every second. Responses were measured from EEG derivations vertex—left mastoid and vertex—right mastoid. Recordings were carried out during two periods of hallucinations and two normal periods, and 75 responses were averaged each time. The first response during each recording period was omitted.

Recording of the auditory evoked magnetic fields

(subject 2) was carried out in a magnetically shielded room; another person was with the patient inside the room. The stimuli were 1000-Hz, 80-dB, 50-msec square wave tones, administered to the subject with a plastic tube once every 0.9 seconds. The magnetic field over the right hemisphere was measured with a first-order SQUID (superconducting quantum interference device) magnetometer (figure 1). The initial recordings were made with a 7-channel axial gradiometer (7), and the second set of measurements was made with a 24-channel gradiometer (8). The 24-channel device has planar flux transformers: two orthogonal figure-of-eight flux transformers measure the derivatives $\partial B_r/\partial x$ and $\partial B_r/\partial y$ of the radial magnetic field component $B_r$ simultaneously at 12 locations, 3 cm apart from each other (figure 1). The planar gradiometer records the largest signal just above the active brain area.

The sensors' exact locations and orientations with respect to the head were determined by recording the magnetic field produced by small coils fixed on the scalp (7). Response amplitudes were measured relative to a 50-msec prestimulus baseline. The equivalent sources were found (by using the simultaneously recorded 24 signals) by a least-squares fit in a spherical volume conductor, adjusted to the local radius of curvature of the head in the measurement area. The first two responses in each recording period were omitted.

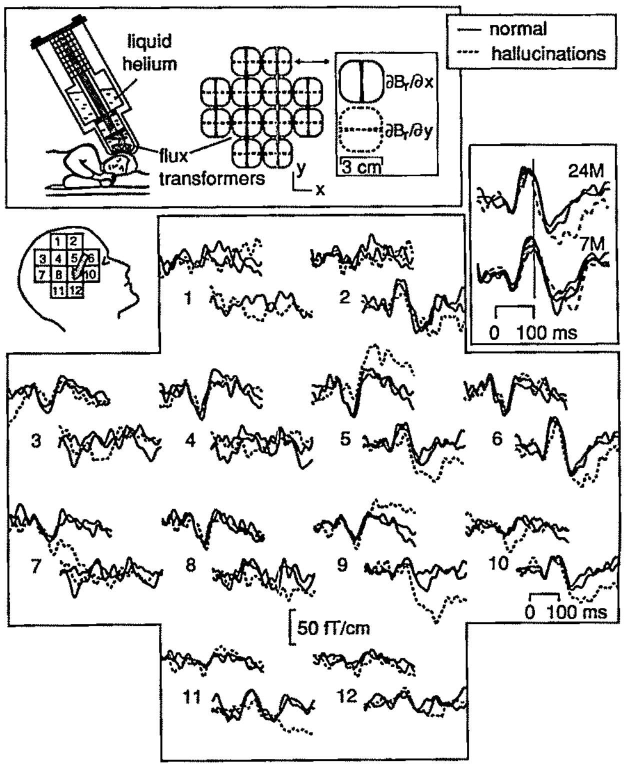
## RESULTS

Auditory evoked potentials were recorded from subject 1 during two hallucination and two normal periods. The main response (N100) peaked at 80 msec during the normal periods but was delayed by about 20 msec during hallucinations. The amplitudes of N100 were not affected, but the late positive potentials over the right hemisphere were slightly increased during hallucinations.

Figure 1 shows the auditory evoked magnetic fields of subject 2 over the right hemisphere, recorded with the 24-channel gradiometer. During the normal periods there were typical auditory responses and a prominent N100m, peaking at 73–94 msec depending on the channel. During hallucinations N100m was narrower; it peaked at 92–98 msec and was dampened in several channels. Further, a late deflection of opposite polarity was seen around 200 msec with a distribution different from that of N100m. Since hallucinations occurred during only one recording period, data are also shown from the earlier 7-channel measurements, in which hallucinations occurred during one recording out of four (the second one). During the normal periods N100m peaked at 80–89 msec, and during hallucinations it peaked at 101 msec. On average, N100m was slightly smaller during hallucinations. The results of these two studies were thus very similar.

The equivalent dipole for N100m explained 90% of the field variance during the normal period (see figure 1, head). The source location is similar to that observed in healthy subjects and suggests activation of the supratemporal auditory cortex (9). During hallucinations the source of N100m was within 1 cm of this site, but the dipole model explained only 73% of the variance.

**FIGURE 1. Auditory Evoked Magnetic Fields Over the Right Hemisphere in a Schizophrenic Subject During Hallucinations and Normal Periods[a]**



[a] The top section represents the experimental arrangement for recording magnetic brain signals. The subject is lying in a magnetically shielded room, and the magnetometer, which has sensors immersed in liquid helium, is placed close to the subject's head. For a description of the flux transformer array, see text. The main figure shows auditory evoked magnetic fields recorded with a 24-channel gradiometer during two normal periods and one period of hallucinations. The passband is 0.05–40 Hz. The recording locations are shown on the schematic head. The upper trace of each pair indicates the field gradient in the vertical direction ($\partial B_r/\partial y$), and the lower shows the field gradient in the horizontal direction ($\partial B_r/\partial x$); both were measured over the same site. The arrow on the head shows the approximate location and orientation of the equivalent dipole during N100m of the normal period. The insert on the right contains responses recorded with the 24-channel and 7-channel devices (24M and 7M, respectively); the 24M recording is the lower trace of pair 6. The main difference in N100m between the normal and hallucination periods is shaded.

## DISCUSSION

Patients who suffer from intense transitory hallucinations but are able to cooperate in research studies are hard to find. We had the opportunity to study two such patients, one with electric and the other with magnetic recordings. In both patients the auditory cortical responses were altered during the hallucination periods. Auditory evoked potential recordings from subject 1 revealed a delay of 20 msec in the peak latencies of N100 but no damping of the responses. In the magnetic recordings of subject 2, similar response delays were observed. The effects were small but replicable. During hallucinations, especially the early part of N100m was dampened, thereby causing the observed peak delay.

The magnetic N100m is evidently generated at the supratemporal auditory cortex (9). At the interstimulus intervals used in the present study, the amplitude and latency of N100m are very resistant to changes in the state of attention: the modification of the evoked responses due to attentional shifts starts only after N100m (10). Therefore, the observed latency differences of about 20 msec cannot be explained by changes in attention. Rather, the delay resembles the effects of speech and music maskers on responses to probe tones in healthy subjects (6). Auditory hallucinations may thus modify activity of the human auditory cortex in a way that is similar to how real (physical) masking sounds do so. Consequently, it seems possible that the auditory cortex is activated during hallucinations not by external input from the ear but by endogenous neural firing.

Retrieval of auditory memories is associated with interaction of the auditory cortex and the mesial temporal lobe, including the amygdala and hippocampus (11). Hallucinations might be caused by malfunctioning of these connections: morphological and imaging studies of schizophrenic patients (12–14) have revealed disturbed cytoarchitecture in parahippocampal areas and atrophy of anterior hippocampus and superior temporal gyrus. The hallucinations reported by schizophrenic patients are typically familiar sounds, such as words or music. Similar "acoustic memories" can follow electric stimulation of the auditory associative cortices, whereas stimulation of the primary auditory cortex elicits perception of elementary sounds, such as buzzing (15). Hallucinations in schizophrenic patients are therefore more likely associated with a distorted interplay between auditory associative areas and the limbic structures, rather than with a malfunction of the primary auditory cortex itself.

## TEXTBOOKS

**Oxford Textbook of Psychiatry, 2nd ed.,** *by Michael Gelder, Dennis Gath, and Richard Mayou. New York, Oxford University Press, 1989, 1,028 pp., $95.00; $45.00 (paper).*

Often lost sight of in today's hectic academic life is the question of what we are trying to accomplish. Certainly, in the minds of most academicians, we are attempting to turn out true professionals whose careers are based on sound and broad knowledge and who have the highest ethical principles and great enthusiasm for their work. To do this, we must have a concept of the breadth, scope, and origins of our profession. In the United States we tend to be rather provincial and believe that we are the world's leader. In truth, we probably are at the forefront of many medical advances, but we have done this with the help of our forebears and our colleagues throughout the world.

Reading the second edition of the *Oxford Textbook of Psychiatry* would go a long way toward rectifying our provincialism. This book presents the scope of British and European psychiatry in a way that few of our trainees have experienced. The textbook has grown from its first edition in 1983 from 883 to 1,028 pages. It is an eminently readable book.

Diagnostically, the authors have chosen to use a draft of the new *ICD-10* nomenclature as well as *DSM-III-R,* which makes the text very useful for audiences in the United States. The overall organization of the book is by diagnostic categories and by specific topics. There are four excellent introductory chapters: "Signs and Symptoms of Mental Disorders," "Interviewing, Clinical Examination, and Record Keeping," "Classification in Psychiatry," and "Aetiology." Chapters on specific diagnoses follow: "Personality Disorder," "Neurosis I," "Neurosis II," "Affective Disorders," "Schizophrenia and Schizophrenia-Like Disorders," and "Paranoid Symptoms and Paranoid Syndromes." "Organic Psychiatry," a splendid chapter, is next, followed by chapters on such topics as psychiatry and medicine, suicide, substance abuse, sexuality, the elderly, mental retardation, forensics, and various treatments.

The book is extremely well written and generally exposes U.S. audiences to traditional concepts as well as concepts that, I fear, are rather "foreign" to us. A good example of the book's comprehensiveness and structure is the chapter on personality disorder. There is an excellent discussion on the assessment of personality and what "abnormal personality" means, a brief but comprehensive section on the history of the term "abnormal personality," and then various classifications and types of personality disorders. There is a brief paragraph on Sjobring's classification, which, I am sure, is unknown to most readers in the United States, followed by a very nice discussion of the general causes of personality disorder that covers such areas as genetics, body build, relation to mental illness, the various psychological theories related to personality disorder, and studies on personality development. With regard to the causes of personality disorder, there is an excellent section on antisocial personality that covers genetic causes, cerebral pathology, childhood behavior problems, and learning theory.

There is no question in my mind that every house officer in the United States would profit from spending several evenings with this textbook. Although it is short on cutting-edge topics such as neuropeptides, molecular biology, and imaging, it more than compensates with its breadth, scope, and clinical phenomenology. In this sense, this text augments our usual teaching and exposes us to the European literature that conveys the breadth and history of our field. It is this perspective that can separate the true professional from the pedestrian worker.

GARY J. TUCKER, M.D.
*Seattle, Wash.*

**American Psychiatric Press Review of Psychiatry, vol. 8,** *edited by Allan Tasman, M.D., Robert E. Hales, M.D., and Allen J. Frances, M.D. Washington, D.C., American Psychiatric Press, 1989, 613 pp., $49.95.*

An excellent reference book for the practicing psychiatrist, this volume has been written for clinicians by recognized experts in the fields of adult psychiatry, child psychiatry, and alcohol abuse to provide in-depth reviews of selected current topics. The textbook is divided into five sections reflecting areas of clinical interest that have been chosen as the subject for intensive review in this edition: Borderline Personality Disorder, Child Psychiatry, Alcoholism, Psychiatry and the Law, and Difficult Situations in Clinical Practice. Each section features a foreword and afterword by the section editors, and each chapter ends with a fairly extensive bibliography.

John G. Gunderson, editor for the Borderline Personality Disorder section, has assembled a series of detailed and scholarly review articles on the epidemiology, pathogenesis, course, and treatment of this disorder. Cognitive-behavior therapy and pharmacotherapy of borderline personality disorder are two burgeoning areas of clinical interest addressed by the authors.

The Child Psychiatry section, edited by Jerry M. Weiner, provides a valuable overview of a number of commonly encountered psychiatric disorders of children and adolescents. The section's limitations appear to be principally a function of child psychiatry's lag in diagnostic refinement and the relative dearth of pediatric epidemiologic studies.

The genetics, epidemiology, neurobiology, and treatment of alcoholism are the subjects of the volume's third section, a collection of state-of-the-art reviews edited by Roger E. Meyer. The prominence of law and its relation to psychiatry provide the focus for the fourth section, edited by Paul S. Appelbaum. This section covers important territory related to issues of psychiatric malpractice, competency, informed consent, involuntary treatment, criminal responsibility, and child psychiatry and the law.

The volume's final section, Difficult Situations in Clinical Practice, edited by William H. Sledge, explores from a psychodynamic perspective some of the prominent sources of strain in psychiatric practice. It deals with issues of countertransference, psychiatric malpractice, the VIP patient, the violent patient, and psychiatrists' reactions to the death of a patient by suicide. The authors extend collegial advice and wisdom derived from clinical vignettes and scholarship as well as their own personal experiences in working with patients.

The volume is surprisingly short on contributions by women. Of the 54 editors and authors, nine of the authors and none of the editors are women. The obvious dominance of male contributors may affect decisions about what areas are reviewed as well as the way subjects are presented for discussion—particularly as they affect female patients and clinicians. Invitations to participate in volumes such as this annual review are important to women in academic psychiatry, whose career advancement may depend on developing name recognition and accruing publications.

Except for the potential for gender bias, this book has few serious faults in its writing and scholarship. The overriding concern of the volume's editors is to provide an outstanding reference text for the practicing clinician, a goal they patently achieve. I enthusiastically recommend this volume to residents, practicing psychiatrists, and other mental health professionals who would benefit from the in-depth reviews offered by these distinguished researchers and clinicians. Given its merits, the volume is well worth the price.

LYNN T. SHEPLER, M.D.
*New Haven, Conn.*

**Handbook of Outpatient Treatment of Adults: Nonpsychotic Mental Disorders,** *edited by Michael E. Thase, M.D., Barry A. Edelstein, Ph.D., and Michel Hersen, Ph.D. New York, Plenum, 1990, 700 pp., $85.00.*

In their preface to this book the editors contend that a confluence of clinical, sociopolitical, and socioeconomic developments in mental health care have made outpatient services "the greatest area of growth" in the field of psychiatry. This *Handbook* was meant to be a "timely and useful" guide to outpatient diagnosis and treatment.

Distinguished contributors, diverse in disciplines and treatment approaches, have written 29 chapters covering the problems and disorders of patients as well as the techniques and concerns of clinicians involved in modern outpatient practice. The book is divided into four sections. In part one, five chapters review general issues of interviewing and diagnosis, differentiation of physical from psychiatric disorders, and drug, psychodynamic, and behavioral treatments in the outpatient setting. Part two contains 14 chapters describing specific disorders, usually concordant with *DSM-III-R* classes of disorders or specific diagnoses. Some departures in content are evident, however, in that chapters on chronic depressive disorders (rather than dysthymia), male sex offenders (instead of paraphilias), and problem drinking (not alcoholism) are included. Part three describes special clinical populations. There are chapters on marital dysfunction, adolescents and young adults, the elderly, Vietnam veterans, mentally retarded adults, and mentally ill substance abusers. The *Handbook* concludes with part four, which contains chapters on ethical and legal issues, the suicidal patient, office practice, and outpatient clinical research.

Although not totally standardized, the individual chapters are generally structured around themes of history, epidemiology or etiologic considerations, diagnosis and differential diagnosis, frequent clinical problems encountered, and specific treatment approaches. I found the chapters to be uniformly high in quality, rich in clinical detail, scientifically sound, and well referenced with extensive, up-to-date bibliographies. Most chapters include very specific suggestions for diagnostic workup and for treatment. For example, chapter 6, "Mood Disorders," includes a step-by-step guide to the outpatient management of treatment-resistant depression. Chapter 9, "Panic Disorder," has a decision tree for a treatment strategy for panic disorder. Chapter 11, "Sexual Dysfunction," gives flow charts for the evaluation of sexual desire problems and erectile dysfunction. Chapter 16, "Alzheimer Disease and Other Dementias," has a table of management techniques for common behavior problems among persons with dementia. Chapter 17, "Selected Organic Brain Syndromes," has tables for reported medical etiologies of delirium, organic delusional syndromes, organic affective syndromes, and organic anxiety syndromes. The chapters on special populations are noteworthy for their emphases on modification or adaptation of standard treatment approaches for patients with special needs.

The coverage of *Handbook of Outpatient Treatment of Adults* is clearly comprehensive. The only patient group arguably not covered are outpatients with chronic schizophrenia, many of whom undoubtedly are maintained and managed in clinics, mental health centers, and community outreach programs after deinstitutionalization. Some clinicians might also wish to have had a chapter on the treatment of personality disorders other than borderline and antisocial, which are discussed. The only other shortcoming of the book is its index, which does not include entries for monoamine oxidase inhibitors or lithium. It is a shame that the practical information filling the pages of this book is not made more easily accessible by a more useful index.

Overall, however, this is a valuable book. For reading and for reference, this *Handbook* deserves a convenient spot on the bookshelf of the clinician in office-based practice.

*New York, N.Y.*

## NEUROLOGY

**Synopsis of Neurology,** *by Richard Lechtenberg, M.D. Philadelphia, Lea & Febiger, 1991, 159 pp., $19.75 (paper).*

In *Synopsis of Neurology,* Richard Lechtenberg, author of *The Psychiatrist's Guide to Diseases of the Nervous System* (1), emphasizes that "the progression of deficits [with neurological problems] is as important as the character of the deficits." His outline of the neurological examination is succinct and generally adequate. We used to include the Chvostek sign, now obsolete because there is no rickets. In cases of syncope, we would gingerly stimulate the carotid sinus.

The elements of history and physical examination occupy 12 pages, and the next 15 pages recommend types of imaging and other laboratory procedures. Ultrasound is left out. Amytal interviews are recommended to establish the integrity of speech, but the scope of Amytal interviews is broader than that. Clinicians and patients deserve wider knowledge of this fairly safe technique.

A compendium is necessarily brief, but some facts in this book are dispersed or conflicting. For example, we are told that pathologies in various parts of the brain can cause anomial aphasia, but later the author says that severe anomias come from a lesion of the left anterior temporal lobe. In 1937 the latter fact was crucial in our diagnosis of George Gershwin's glioblastoma.

We are also told that hypomagnesemia can cause convulsions. In reference to eclampsia, however, the author calls the use of magnesium sulfate "inappropriate" for the "seizures." At Los Angeles General Hospital, where magnesium sulfate injections for eclampsia were initiated by Emil Bogen in 1924, this is still standard treatment, along with emptying the uterus. Dr. Lechtenberg tells us that carbamazepine is a relatively safe medication for the treatment of epilepsy in a pregnant woman.

He also asserts that neurological abnormalities due to thyroid deficiency are all remediable by thyroid substitution. We beg to differ. Pat Brownstein demonstrated years ago that cretinism can be corrected by thyroid if it is administered very early. If endocrine therapy is delayed to 3 months, however, the baby's chance of normal intellect is reduced, and it is further reduced the later the thyroid is started.

The author calls attention to intrauterine rubella infections as the cause of childhood defects, including what Leo Kanner called autism. Unfortunately, immunization against German measles is not universal, and the incidence of viral encephalitis has hardly decreased. We understand that the vulnerable period is the second trimester of pregnancy.

This book covers Alzheimer's disease adequately but fails to point out that memory or other deterioration typically begins before the age of senility. Dr. Lechtenberg properly warns that, "if the disease occurs before the age of 60, brain biopsy may be necessary to exclude treatable causes of dementia."

Parkinsonism is given almost current coverage. The International Parkinson Conference offers "hope . . . that fetal dopaminergic cells may represent a . . . source of [transplanted] tissue able to grow and compensate for the lost dopaminergic neurons in the Parkinsonian brain." Tissue transplantation for parkinsonism was also the subject of many papers scheduled for the 1991 meeting of the American Academy of Neurology. Although Dr. Lechtenberg displays a good knowledge of Wilson's disease, he omits the characteristic "rhisus sardonicus" and "wing flapping."

*Synopsis of Neurology* is a bit short on therapy. The new botulinum toxin treatment is of interest in the treatment of movement disorders. It is injected locally for dystonia, torticollis, writer's cramp, and blepharospasm. Presumably it acts solely at the neuromuscular junction.

In the excellent section on stages of sleep in the chapter "Sleep Disorders," credit is due to the discoverer of sleep stages, Nathaniel Kleitman. We wonder if sexual tension or stress is not a cause of "insomnia" and if sexual release is not a natural and effective treatment if there is no organic causal disturbance.

Dr. Lechtenberg devotes a paragraph to poliomyelitis, even though it has been practically eliminated in the United States through the use of two vaccines. Multiple sclerosis is well covered; the author published a fact book on the subject in 1988 (2). We used to suspect multiple sclerosis from a triad of scanning speech, bitemporal pallor, and intention tremor. Some still consider the CSF specific.

Dr. Lechtenberg's advice on subdural hematoma is astute. We too watched for late lapses into drowsiness or unconsciousness; inequality of the pupils was our signal "to go in."

We may have misunderstood the remark about the transiency of headache and hypertension from pheochromocytoma or the combination of monoamine oxidase inhibitors and tyramine-containing foods. These are dangerous situations, requiring instant antihypertensive medication and removal of causative agents.

A minor matter—those of us who know the imposing personality of Foster Kennedy do not put a hyphen between Foster and Kennedy. As for tinnitus, one is led to look for serious involvement of the eighth nerve, but many mild cases of tinnitus are best ignored. Strangely, in the chapter "Congenital Disorders," no specific reference is made to inborn errors of metabolism or amino acid deficiencies, such as phenylketonuria, although these are implied.

Happily, the author does address ataxia telangiectasia. Elena Boder has described these cases through many years. Their origin is now localized to chromosome 11.

There are many other fine chapters. *Synopsis of Neurology* is the distillate of an apparently wise clinician's expertise. Keep a copy of the paperback handy in your briefcase or examination kit. We will do likewise, and we look forward to meeting Dr. Lechtenberg somewhere sometime.

*Los Angeles, Calif.*

**Merritt's Textbook of Neurology, 8th ed.,** *edited by Lewis P. Rowland, M.D. Philadelphia, Lea & Febiger, 1989, 928 pp., $67.50.*

A book that appears in its eighth edition must have a great deal to recommend it. The first edition of this book (1955) and the next five editions were prepared entirely by Professor Merritt himself. He died in 1979, and the present book is a fitting memorial to him. The tremendous influence of Dr. Merritt on neurology in the United States is demonstrated by the 70 contributors who were his students, 30 of whom have become heads of departments or professors throughout the country. The march of progress threatens to make obsolete this textbook, like all books, requiring more frequent revisions, but since the introduction of magnetic resonance imaging (MRI), the AIDS epidemic, and Lyme disease, little has occurred that would render useless a text that is only several years behind the times. For example, the explosion of molecular genetics occurs at too great a rate for even monthly journals to keep pace, but *Merritt's Textbook of Neurology* provides a solid background against which the new discoveries may be organized.

This volume starts with a section entitled Signs and Symptoms of Neurologic Disease that includes delirium and dementia; aphasia, apraxia, and agnosia; syncope and seizure; coma; pain and paresthesias; dizziness and hearing loss; impaired vision; headache; involuntary movements; syndromes caused by weak muscles; gait disorders; and "signs and symptoms in neurologic diagnosis." Following this section, the book is organized around disorders rather than anatomy. First the conditions of known etiology are presented, including infections, vascular diseases, tumors, trauma, birth injuries, and genetic diseases. Then the neurological disorders of uncertain etiology are discussed, including particularly good sections on cerebral degenerations of childhood by Isabelle Rapin and on movement disorders and spinal cord disorders by authorities of the stature of Stanley Fahn and Rowland himself.

The discussions of head injury, cerebral palsy and mental retardation, autism, and pain syndromes are particularly lucid and useful for psychiatrists.

This is not a "how-to-do-it" book but assumes knowledge of the neurological examination, neuroanatomy, and various laboratory procedures of neurology. There are excellent illustrations of CT scans and MRI scans that have been updated by the Radiology Division of the Neurological Institute of New York.

Inevitably, a text must be compared with other texts, and the necessary deficiencies of an edited book with many authors must be weighed against the advantages of having 70 experts produce essays in their areas of expertise rather than having one person try to cover a field as vast as the human nervous system. *Neurology* by Mark Mumenthaler (1) is also organized around diseases and has been a standard text in Europe since the first German edition in 1967. *Merritt's Textbook,* on the other hand, is a distinctly American book. Mumenthaler's *Neurology* is written by a Swiss professor and has been published in 10 languages to date. *Merritt's Textbook* lacks the beautifully diagrammatic neuroanatomical illustrations and the emphasis on practical physical diagnosis of Mumenthaler's *Neurology.* One might have the best of both worlds by getting *Merritt's Textbook* for its state-of-the-art discussions of pathology and biochemistry and supplementing it with *Neurologic Differential Diagnosis* by Mumenthaler (2), which is a short (156 pages with index) volume of syndromes and symptoms diagramed in functional neuroanatomical detail with tables and charts that would allow a reader with even rudimentary knowledge of the physical examination to become expert in neurological diagnosis. *Merritt's Textbook* would be most useful to psychiatrists who wish to be informed about diseases of the nervous system, but it would not provide enough information to the novice to allow hands-on diagnosis or treatment of patients with neurological problems. That is not necessarily a flaw because the text is a reference rather than a tutor. *Merritt's Textbook* makes excellent reading, and it is remarkably inclusive for a standard-size book.

Although neurology is thought of as "hard" science, it soon becomes clear that this specialty lacks a diagnostic and statistical manual. It also lacks the controversies that go along with attempting to find such a consensus. *Merritt's Textbook* does not touch the active debate going on regarding the international classification of headaches. It also essentially steers clear of the most important functions of the brain—thought, emotion, and human consciousness—except in the introductory chapters, where the treatment of "behavioral neurology" is quite inadequate for the practicing psychiatrist who wishes to understand the complicated relationships of brain and behavior that are perturbed by human disease. Lishman's *Organic Psychiatry* (3) is a necessary companion to either *Merritt's Textbook* or Mumenthaler's *Neurology.* There is as yet no textbook that discusses the higher cognitive and emotional effects of the hundreds of known neurological syndromes. Those wishing to perform their own synthesis of brain and mind would be well-advised to use *Merritt's Textbook of Neurology* as an authoritative background reference.

## CHILD PSYCHIATRY

**Concise Guide to Child and Adolescent Psychiatry,** *by Mina K. Dulcan, M.D., and Charles W. Popper, M.D. Washington, D.C., American Psychiatric Press, 1991, 241 pp., $21.00.*

I was skeptical about the idea that a pocket-sized text could offer a clinically useful and comprehensive overview of the most salient aspects of child and adolescent psychiatry. Concise guides more often seem suited to books on travel and home repair. However, the authors have produced an excellent resource for beginning clinicians as well as for those with more experience who only occasionally see children with psychiatric problems.

The authors begin by reviewing general issues in the evaluation and treatment of children and adolescents with psychiatric disorders. This section offers a brief orientation to the unique aspects of child psychiatry and is loaded with useful clinical information—from play materials that may facilitate a more comfortable interview (e.g., washable markers) to tables summarizing the instruments available for intelligence and academic testing. The next several chapters review the clinical features, epidemiology, etiology, course, prognosis, evaluation, differential diagnosis, and treatment modalities for axis I disorders. The sections on clinical features are informative and clear, but the sections on etiology may suffer from the concise guide format. The chapter reviewing schizophrenia and disorders of substance use, mood, anxiety, sleep, and adjustment is brief and probably does not reflect the relative importance of these disorders in the practice of child psychiatry. The last three chapters cover special clinical circumstances (e.g., emergencies, divorce, and chronic medical illness in children), psychopharmacology, and psychosocial treatments. The chapter on psychopharmacology is perhaps the best suited to the concise guide approach and will be particularly helpful to general psychiatry residents wrestling with medication doses for children. Together, these three chapters present a wide range of relevant information on assessment and treatment in a clear and easily accessible format. Finally, the authors include an appendix for parents, referencing books on problems that range in severity from sibling rivalry to schizophrenia. This is a book to be used, not one to be relegated to a space on the shelf.

JOSEPH PIVEN, M.D.
*Iowa City, Iowa*

**Recognizing Child Abuse: A Guide for the Concerned,** *by Douglas J. Besharov. New York, Free Press, 1990, 270 pp., $24.95.*

Reviewing books is a snap. All you need is catholic reading tastes, good typing skills, and a titanium-lined digestive system. Strong stomach? In this case, yes. *Recognizing Child Abuse* is an unusual work that uses gut-wrenching text and pictures to present nearly everything needed to deal with children who have been neglected, physically abused, or sexually assaulted.

After an introductory overview (more than 2 million reports of child abuse were made in 1987) we learn the legal pitfalls of whom, what, and when to report; the rights and responsibilities of the reporter; and the likely consequences should the duty to report be neglected.

Much of the information is bundled into charts (48 of them), handy for a quick review. Chart 3-2 spells out what must be reported—a dozen types of abusive behavior, including neglect to respond to a child's emotional and educational needs. Although under 10% of reports are knowingly false, hot lines are often clogged with instances of delinquency, truancy, and other behaviors outside the intended scope of the statutes. Another chart lists conditions of poor environmental conditions that are often overreported as neglect.

A major problem for professionals and lay persons alike is discriminating abuse from reasonable punishment. Chart 7-1 helps with this problem. The author also discusses frequently observed "suspicious" injuries, categorized by age of child, and provides illustrations courtesy of John Craig and CIBA. This section is not for the faint of heart.

Sexual abuse is examined from the twin perspectives of the physical evidence and the victim's behavior. The author cautions us not to use the latter alone as the basis for making a report—children can be excessively shy or overly friendly for reasons other than abuse.

Besharov is a consummate advocate for children. He would take preventive action when a parent appears incapacitated by schizophrenia or severe depression. This approach may make some patient's rights advocates squirm. Not surprisingly, he backs up his arguments with several charts, including a listing of suspicious behaviors that might be observed on a maternity ward.

Later chapters explain how to make a report (what to include or leave out) and how to preserve evidence. The author advises parents on how to seek help if they suspect a child is being abused or if they themselves are reported for abuse.

If this book has a flaw, it is that it is sometimes encyclopedic without being specific. For example, it states that laws in half the states allow medical professionals to hold endangered children but does not say which half. I wanted a table (surely, the author must have had one more chart in him) comparing the requirements of different jurisdictions. There is an appendix listing child protective agencies in 54 states and territories.

*Recognizing Child Abuse* is a thorough, compelling, and readable work that I strongly recommend for any professional who treats children or their parents. But keep the antacids handy.

JAMES MORRISON, M.D.
*Martinez, Calif.*

**Clinical Aspects of Child and Adolescent Development: An Introductory Synthesis of Developmental Concepts and Clinical Experience, 3rd ed.,** *by Melvin Lewis, M.B., B.S., F.R.C.Psych., D.C.H., and Fred R. Volkmar, M.D. Philadelphia, Lea & Febiger, 1990, 445 pp., $42.40.*

Books become classics when they provide essential information, maintain timeliness, are well received by an audience, and offer insights not obtainable from other sources. *Clinical Aspects of Child and Adolescent Development* can be considered among the classic textbooks in child and adolescent psychiatry. This is the third edition of the text, which was originally published in 1971 with the goal of providing the medical student with "an introductory synthesis of certain basic psychological concepts and their use in understanding the wide range of behaviors seen during the stage of human development we call childhood" (p. vii). The third edition has been updated and extensively revised. The text follows a pedagogical concept that "views medical education as a kind of spiral process, in which the student first goes once over lightly, and relatively briefly, the broad sweep of the curriculum. At subsequent periods he can then go over similar ground, this time with more familiarity and greater depth" (pp. vii–viii). The preface to the third edition notes that the theoretical framework for this book is based on the "struggle with the multiple theories we now have to account for human behavior. Explorations of the biology of the cell and the psychology of the unconscious continue to account for bits of human behavior, in some cases better than in others" (p. ix).

The book describes longitudinal, cross-sectional, and developmental perspectives of normal and pathological development and focuses on pediatric and psychiatric disorders and treatment. This third edition enlarges the scope of developmental processes to integrate descriptions of childhood and adolescence. The book is very comprehensive and remarkably easy to read. The text is specific and brief and clearly explains concepts in an objective way. A unique feature is that at the end of most chapters, brief annotated notes are included to illustrate statements from primary source books or papers. The authors' purpose was to expose students to concepts presented by theoreticians, researchers, and clinicians who have made major contributions to the field of child development and psychiatry. There are ample figures, tables, and illustrations that emphasize concepts and make it possible for a student to more easily synthesize the material and gain a greater depth of understanding.

A number of other features of the text are noteworthy. Chapter 23, "The Psychiatric Evaluation of the Infant, Child, and Adolescent," is a comprehensive review of factors to be assessed during a mental status examination of children or adolescents. This chapter can be useful as a guide for both inexperienced and experienced clinicians to organize a complete mental status examination. The chapter on differential diagnosis presents the rationale of why formulating a differential diagnostic assessment in children is so difficult, especially since diagnostic classification has not been sufficient to capture precisely the entire spectrum of child psychopathological presentations. Other problems in diagnosis include reliability of informants and lack of reliable measures of childhood symptoms. The chapter attempts to discuss a number of diagnostic issues such as attention deficit disorder, bed wetting, hallucinations, language and speech dysfunction, reading difficulty, seizure behavior, sleep disturbances, spelling difficulties, stealing, temper tantrums, social isolation, thought disorder, and violent behavior. However, it omits such important problems as depression, anxiety, and eating problems.

The chapters on childhood and adolescent psychopathology clearly present highlights of specific syndromes that nicely complement previous chapters on assessment and differential diagnosis. The two chapters on treatment outline features of psychodynamic psychotherapy and psychopharmacology. Concepts of interpretation during psychotherapy and psychotropic-prescribing guides are presented informatively, clearly, and concisely. A shortcoming evident throughout the text, however, is that a greater number of more recent references could have been provided. Nevertheless, the scope of material covered is pertinent and up-to-date.

In summary, this text should continue to be considered a classic. There are few textbooks that address the needs of students with beginners' backgrounds in child and adolescent development and psychopathology. This book strongly meets the need for education, review, and synthesis. Dr. Lewis is a skilled and outstanding teacher and clinician, and Dr. Volkmar, who joined Dr. Lewis in writing this third edition, has helped to widen the scope of the material. I highly recommend this book, which should be especially available in medical school libraries.

*White Plains, N.Y.*

**Giant Steps: Therapeutic Innovations in Child Mental Health,** *by Lee Combrinck-Graham. New York, Basic Books, 1990, 291 pp., $27.95.*

The central thesis of this book is that there currently exists a crisis in the delivery of mental health services to children. According to the author, the reason for this state of affairs is that there are more children in need of treatment than there are available qualified service providers. To surmount this problem, she advocates a reconceptualization of mental health within a systems theory perspective. At the practical level, major innovations in treatment are required; these innovations are referred to as giant steps.

The book consists of three main sections. Part one focuses on childhood development with respect to proximal and distal social systems surrounding the child. The first giant step, according to the author, requires recognizing that there are multiple realities encompassing different aspects of the person's experience. Thus, to effectively address mental health problems, differing perspectives obtained from various vantage points need to be integrated into interrelated and meaningful systems. This section of the book advocates that application of the systems theory framework to diagnosis and treatment be the first step in resolving the mental health service delivery crisis.

Part two elaborates on the contextual basis of psychopathology as well as its diagnosis and treatment as discussed from the systems theory perspective. Particular emphasis is placed on the family system. The giant steps here pertain to evaluating and recasting the components of the system promoting psychopathology or behavior disorder.

Part three examines key macrosystems—the health, legal, social, and educational environments in which mental health disturbances need to be identified and treated. Numerous case anecdotes, buttressed by the author's personal opinion, are interspersed in the discussion. This aspect of the discussion frequently has a polemic quality. Although the author is to be commended for emphasizing the contextual basis of mental health problems in children and applauded for suggesting the need for giant steps, she unfortunately offers no plan for implementing changes. She offers only the pessimistic conclusion that the needed changes are not likely to happen in the foreseeable future. The fact of the matter is that major initiations currently underway are devoted to developing an integrated systems approach to mental health problems.

The main contribution of this book is its emphasis on person-environment interaction. This may appear mundane; however, the reader is reminded that psychiatry today emphasizes the biological mechanisms underlying psychopathology without a complementing emphasis on the psychosocial environment. The poor quality of fit between the person and the environment as the primary basis of maladjustment is not well integrated in current diagnostic and treatment practices. By advocating for the systems theory perspective and, accordingly, for a paradigm shift in diagnosis and treatment, this book makes a useful contribution.

Certain shortcomings of this book are notable, however. The author does not address issues and problems regarding the health policy environment and training needs of professionals. She gives virtually no attention to the research literature of the past two decades. Consequently, for the informed reader, the material presented in this book is superficial and lacking in critical analysis. It is sometimes difficult to decipher what the author means exactly. For example, in one paragraph under the heading "Acting Like a Mental Health Professional," she states, "Mental health is not a place and it is not a service." Two sentences later she exhorts professionals to "offer mental health services." The lack of precise communication weakens the book.

In sum, this book is a heralding call for a systems change rather than an empirical analysis of the problems associated with the diagnosis and treatment of psychopathology.

## PSYCHOANALYSIS

**Psychoanalysis: Toward the Second Century,** *edited by Arnold M. Cooper, Otto F. Kernberg, and Ethel Spector Person. New Haven, Conn., Yale University Press, 1990, 220 pp., $27.50.*

This book celebrates the 40th anniversary of the Columbia University Psychoanalytic Center. This psychoanalytic institute, one of few within a university, has represented a liberal pole in the debate between right- and left-wing theorists in the issue of whether to replace Freud's early libido theories. This debate leads to four domains for new theories, each a section in this book: Culture, Drives, Self, and The Interface of Mind/Brain Levels of Explanation.

Libido theory started with an evolutionary slant on sexual drives. Later, the person was seen as enmeshed in a social field that imposed psychological sexuality on the biological core of instinct. Culture had to be considered. By a courageous refusal to accept dogma, Rado, Kardiner, Levy, and Daniels—founders of the Columbia Institute—established a path of integration among individual psychology, psychoanalysis, and social disciplines such as anthropology.

Psychoanalysis brings its own observations to this intertheoretical effort. Transference phenomena are an example. In the section on culture, Person beautifully details how clinical supervision and transference patterns replicate across social frames of treatments and training. Also in this section, Kernberg describes how social processes such as repetition of political frustrations in the mass media can affect the individual in terms of progression and regression in views of self and others. One result may be evocation of a regressive yearning for an idealized leader. That can lead to endorsement of leaders whose paranoia and narcissism then assume malignant proportions through ascension to unchecked political power.

In the second section, Drives, Cooper rejects the early psychoanalytic explanation of emotions as derivatives of instinctual drive energies as too limiting for modern and future theories. Karush describes three new hypotheses within current psychoanalytic theory: emotion as part of all ideas and personal schemata, complex affects as signals and symbols, and the power of figures of speech to redirect the expressions and representations of emotionality. Sandler summarizes complex motivation theory as including goals of safety and control over states of mind. Viederman points to the role of ideals, self-schematization, and desires to change as effectors of mental activities and life-planning choices. The section on drives ends by setting the stage for chapters in the next section.

In the third section, Self, Meyers shows how Freud's language contains many modern concepts of self. Michels, Schafer, and Stern each presents a separate point of view. All point to future theoretical developments that can handle issues of multiple self-schematization in a single individual and the development of supraordinate meaning structures.

The final section deals with the mind/brain. Person reviews the mind/body dilemma of philosophy, setting the stage for Cooper's final chapter, a fine refutation of neurocomputational reductionism.

MARDI HOROWITZ, M.D.
*San Francisco, Calif.*

**Psychoanalytic Knowledge,** *by Eugene B. Brody. Madison, Conn., International Universities Press, 1990, 246 pp., $30.00.*

This is a puzzling book that analyzes psychoanalysis from outside and inside at the same time. Many defects of the psychoanalytic system are delineated with clarity: its dependence on an archaic psychobiology, the resemblance of psychoanalytic organizational structure to that of an organized religion, the importance of hierarchical structure as an impediment to sober challenge, the economic forces that reward individual psychoanalysts for creating new co-religionists who themselves must find new acolytes in order to recover the cost of their education, and the tendency of a protracted and closely monitored training program to reward conformity rather than creativity, which is viewed as dissent or failure to comprehend.

Brody answers each criticism lovingly—all are valid, and each has meaning that must be understood within the system of psychoanalysis itself. All of these flaws, these contradictions between a professed openness to investigation and the rigid framework within which it may be expressed, are evaluated in terms of the profound benefit to be achieved by immersion within the system. We learn here that a rigid orthodoxy may protect a fluid discipline, that each worker deserves reasonable pay, and that newer science allows us to replace archaic theory with modern reason while still retaining the beauty of the original construction. This is a lover's book, full of the joy to be experienced when one gives up resistance and dives into the unknown accompanied by a psychoanalytic guide.

One cannot ask for a more articulate introduction to the dilemma in which modern psychoanalysis is caught up. The observer who remains outside the fold must see psychoanalysis as a template, a structured mode of inquiry that offers powerful understanding even as it distorts the field it views. Not to know its special contribution is to remain naive, ignorant of the inner world that governs so much of our experience. Such understanding may not be possible without the willingness to accept theories and rationales that are clearly flawed, but those who do accept, join, immerse themselves, and eventually belong seem inevitably to lose their ability to step outside the system and see explanations, treatments, and, indeed, world views impossible from within.

Like most articulate and intelligent members of the psychoanalytic community, Brody has his own system of patches to place on this leaky vessel. Suggested is an information processing model for the unconscious and an anthropological outlook that takes this adjustment of theory into the larger community. Everywhere Brody is interesting and informative, scholarly and entertaining. Yet the entirety of this slim volume serves to justify the author's assertion that *Psychoanalytic Knowledge* is available only from within the fold of psychoanalysis.

DONALD L. NATHANSON, M.D.
*Philadelphia, Pa.*

**The Human Core: The Intrapsychic Base of Behavior, vol. 1,** *by Leo Rangell. Madison, Conn., International Universities Press, 1990, 478 pp., $60.00.*

**The Human Core: The Intrapsychic Base of Behavior, vol. 2,** *by Leo Rangell. Madison, Conn., International Universities Press, 1990, 500 pp., $60.00.*

A generation of psychoanalysts and psychoanalytically oriented clinicians in the United States looked to the ego psychology "school" of Anna Freud and the triumvirate of Hartmann, Kris, and Loewenstein and their disciples as the leading edge of the true Freudian doctrine. It is to this generation that Leo Rangell belongs and it is in this doctrine that his "core" is centered. *The Human Core* comprises selected papers by Rangell that he believes reveal a connected theme, namely, the ongoing unconscious intrapsychic process. He has a particular interest in what he describes as the unconscious decision-making function of the ego. His contribution is to elaborate the clinical and theoretical aspects of this "ego function." He also presents the related theme of structural levels of anxiety. At the first level is anxiety signaling an unacceptable impulse. This leads to some defense (e.g., repression), creating an oppositional conflict between ego and id. A second level of anxiety will arise if repression cannot deal with the state of increasing psychic tension. This second-level signal anxiety can in turn produce inhibitions, symptoms, and greater anxiety. Rangell believes that his structural theories (which I have by necessity grossly oversimplified) are a working out of the ideas of the later Freud, Hartmann, and David Rapaport. Rangell's goal is to use this structural approach to produce a psychoanalytic theory of action and to resurrect some psychoanalytic notion of will and of moral responsibility.

Certainly Rangell has chosen important theoretical objectives, but, unfortunately, I do not think he achieves them. For example, commenting on the legal issue of criminal responsibility, he suggests that his ego psychology would propose a spectrum of responsibility instead of the duality of responsible versus irresponsible. This idea is neither useful nor original, but Rangell seems to know that most of his potential audience has headed for the exits. By the time one gets to the end of these two volumes it is clear that Rangell is not happy about the state of things. Freud used to be in; now he is out. In "politically correct" circles, Freud is considered patriarchal, authoritarian, unfeeling, and doctrinaire, and so are Rangell's true Freudians. It is not just that potential patients are wary and that Freud is in bad odor, Rangell believes that ego psychology, a valuable scientific paradigm, is being destroyed from within by the negative paradigms of other psychoanalytic perspectives.

What Rangell seems unwilling to consider is the possibility that the many critics and defectors are correct in realizing that ego psychology is in fact a blind alley. The structural approach in its reification of human subjectivity understood everything and therefore understood nothing. Reified theory soon loses its explanatory power, and the "human core" thus understood has lost its defining capacity of surprise.

Freud's genius had an oppositional streak. He loved to stand things on their head and confound his readers' expectations. Indeed, as long as Freud lived he felt free to see afresh. One can quote Freud against Freud on many crucial issues. There is, therefore, no true Freudian doctrine; there is only the possibility of an encounter with Freud's genius. Those who dismiss Freud without reading him because he is no longer politically correct are Philistines. However, those who claim to quote the true Freud and preside over his temple are the pharisees.

Rangell has a human spirit too generous and searching to be cabined by the pharisee label. His own psychological and intuitive gifts as a psychoanalyst rescue him from the level emptiness of the ego psychology theory to which he has given his allegiance. One sees his gifts most clearly when he either shares his nuanced reading of Freud or reports his own clinical insights into his patients. Unfortunately, much of what he writes deserves to be ruthlessly edited, but the reader who perseveres will emerge from the thickets every few pages and catch a glimpse of something worth the effort. *The Human Core* is a defense of the true faith; it is unlikely to attract converts.

**Drive, Ego, Object, and Self: A Synthesis for Clinical Work,** *by Fred Pine. New York, Basic Books, 1990, 269 pp., $25.95.*

Despite its many critics, internal controversies, and historical vicissitudes, psychoanalysis remains the mother of all personality and clinical theory. The longevity of psychoanalysis has guaranteed evolution in theorizing and the development of competing models for understanding what psychoanalysis is, the nature of its subject matter, and how it works. Competing understandings of what psychoanalysis is and the nature of its subject matter have been the sources of intense squabbles among psychoanalysts. The history of the psychoanalytic movement, not unlike religious movements, has had its shibboleths of orthodoxy and faithfulness to the vision of its founder and, in cases of divergence, accusations of heterodoxy, excommunications, and schisms. Freud's work itself contains many contradictions and revisions across his lengthy career, and, when examined closely, Freud's work lacks the internal coherence that one might rightly expect in a unified theory. Freud's models of the mind—the reflex arc, structural and topographical theories—are but one example. Many critics and psychoanalytic theorists have deplored the multiplicity, pluralism, and lack of theoretical unity in the discipline.

Rather than deploring psychoanalytic pluralism, Fred Pine sees the "four psychologies of psychoanalysis" as powerful tools at the service of the clinician. Pine takes the well-known history of clinical psychoanalysis—from classical drive theory and Freud's nascent ego psychology through ego psychology proper to the emergence of object relations theory and, finally, self psychology—and views these as alternating and interrelated perspectives for viewing and doing psychoanalysis and psychoanalytic psychotherapy. Pine stresses that any psychological event may be described from four functional points of view—in relation to drive gratification, ego functions, object relations, and self experience. Pine's thesis is that this multiplicity is a source of strength, and he sets out to demonstrate the usefulness of alternating frameworks for understanding human development, clinical concepts (for example, the concepts of motivation, ego defect, and preoedipal pathology), and work with individual patients. Rather than decrying their competing claims and perspectives, Pine sees them as tools at the disposal of the practitioner.

Pine's presentation of his argument is couched in a scholarly but jargon-free "experience-near" conceptualization, without contesting (or even addressing for that matter) the underlying assumptions and claims of each approach. The chapters on symbiosis and preoedipal pathology are especially rich. His approach, consistent with most modern psychoanalytic theory in the United States, is a sort of psychoanalytic psychology without metapsychology. The pragmatism and utilitarianism advocated here could, perhaps, have been written only by an American psychoanalyst.

Pine looks at personality development in terms of the four psychologies and through detailed vignettes of clinical cases, illustrates how "moments" in treatment (in the context of evenly suspended attention) can be alternatively conceptualized and serve as the basis for intervention. Indeed, Pine would have us believe that a complete analysis or psychotherapy may necessarily bring all of the perspectives to bear in work with the individual patient at one time or another.

Many, especially those deeply wedded to the assumptions and claims of one or another of the four psychologies, will find Pine's syncretism and leveling of these approaches objectionable and controversial. Others, especially trainees, who are not burdened by the baggage of loyalty conflicts and previous commitments, may find Pine's ideas quite compatible and not particularly revolutionary. One must admit, however, that each of the four psychologies does indeed have its own milieu, language, and technical variations. Again, not unlike religion, the true colors, feel, and nuances of a perspective or world view do not emerge unless viewed from a committed outlook.

I do not think that Pine's eclecticism is a substitute for immersion in the viewpoints espoused by the adherents of the four psychologies of psychoanalysis. Nevertheless, Pine's work is well written, clinically insightful, and very modern and provides the practitioner with the tools to broaden and deepen listening, understanding, and intervening.

**The Annual of Psychoanalysis, vol. XVIII, 1990,** *edited by the Chicago Institute for Psychoanalysis. Hillsdale, N.J., Analytic Press, 1990, 231 pp., $29.95.*

This annual was a pleasure to review. It contains four sections that give a broad range of current ideas, predominantly focusing on a self psychology perspective. Although other theoretical perspectives are not included, I found the book very stimulating and would encourage psychiatrists to look at this annual and select articles of interest. All have substantial clinical relevance.

The first section, Developmental Studies, includes two papers. The first is on the developmental psychology of the self and the changing world view of psychoanalysis. The authors of this chapter review the evolution of classical psychoanalysis and Freud's assumptions, which were based on the scientific world view of his time. This evolution progressed to a "postmodern" view of science, which embodies a world view based on the study of individuals over time from the point of view of their own experiences rather than in terms of functions and mechanisms. The authors attempt to show how people maintain a sense of integrity by attending to an understanding of the subjectivity of the individual. They recommend making an empathic comprehension of meaning and motives the goal of psychoanalytic investigation. This is a very scholarly paper that brings the reader up to modern-day self psychology perspectives and to psychoanalysis in the 1990s. The other chapter in the first section is a very creative treatment of the interface of developmental psychoanalytic psychology and the changing understanding of the organization of the brain.

The next section includes four papers on clinical studies, including such areas of interest as what happens in therapeutic stalemates and what is the nature of the therapeutic interaction. A paper that should be of interest to many is one on varieties of therapeutic alliance by Brandchaft and Stolorow, who examine the bond between the analyst and patient, recognizing that the establishment of this bond is of primary importance in the conduct of good psychoanalytic work. In the ego psychology view, the understanding of resistance comes from conflict solely within the patient. The authors aptly state that ego psychology analysts require the patient to identify with the analyst's view of himself or herself as essentially neutral in relation to the patient's conflicts. The authors focus their arguments on the largely unchallenged assumption in ego psychology and object relations psychoanalysis that there is an objective reality known to the analyst. The authors acknowledge and elaborate on the work of Evelyn Schwaber in her focus on the importance of attending to the patient's subjective reality and the goal of the analyst's stance, which is to understand the experience of the analytic process from the patient's perspective.

The third section includes two papers. "Object Versus Self-Object Studies" by Estelle and Morton Shane addresses the process of mourning and contrasts object loss with self-object loss in both adults and children. The authors attempt to enrich our understanding of the importance of self-objects in mourning the loss of a significant other for adults as well as for children. The second paper contrasts the transitional object with the self-object concept in relation to the treatment of patients with borderline personality disorder.

The final section of this annual contains theoretical and historical contributions. There is a wonderful article on postanalytic amnesia, clarifying the normality of remembering very little of the therapeutic process. There are also two excellent papers on hypnosis and its relationship to psychoanalysis and on Freud's views as they evolved through his life as well as the concepts developed since Freud's time that reflect the changes in psychoanalytic theory. The final paper is an illustrative mathematical model of affects.

Overall, I found this book to be another major contribution to psychoanalysis. One who reads this annual will feel much more abreast of current psychoanalysis.

## SEXUALITY

**Incest-Related Syndromes of Adult Psychopathology,** *edited by Richard P. Kluft, M.D. Washington, D.C., American Psychiatric Press, 1990, 293 pp., $32.00.*

We are most comfortable with patients who are most like us, treating them with empathic sensitivity and the profound respect we wish for ourselves. To those whose illnesses make them so unlike us that they may be regarded as barely human, we offer the surcease of purely somatic therapies, protective incarceration, and massive disavowal of their inner lives.

*Incest-Related Syndromes of Adult Psychopathology* is a passionate and disciplined book about a grubby little subject that nobody likes. Maybe it was acceptable to nod tolerantly and dismiss incest when we were taught that it "happened" in fewer than one in a million families. But there is no taboo against incest—there is only a taboo against talking about it. The real frequency? Perhaps nearly all of those with multiple personality disorder, many or most of our immense and growing population of male and female prostitutes, and a surprisingly high percentage of those with "borderline" personality disorder.

The editor of this book, Richard P. Kluft, has devoted his career to the study and treatment of those among us who have been the most damaged by actual psychic trauma. He has assembled a group of talented and dedicated clinician/scientists whose work now requires us to look for evidence of incest with an urgency directly in proportion to the amount of chaos seen in our cases. Kluft's opening chapter, itself of a literary quality rarely found in clinical texts, models the sort of self-examination necessary to the lysis of disavowal. It is not that we have never come across cases of incest, he says—they were the promiscuous sisters of our high school buddies, the "easy lays" of our own years of sexual yearning. In his closing chapter, Kluft drives home a message even more difficult to face—the experience of incest makes the victim a "sitting duck" for sexual interaction with teachers, therapists, and religious authorities. Whoever has been used sexually by his or her caregivers remains compelled to repeat such scenes of abuse until some careful clinician recognizes this form of seductiveness as a specific message within the transference.

Many of the other authors echo the editor's concern. Diane H. Schetky reviews the literature on long-term and late-appearing sequelae of childhood trauma. Bennett G. Braun demonstrates the relation between severe child abuse and dissociative disorders like multiple personality disorder; the average professional reader is likely to experience some dissociative symptoms on reading his chapter. Philip M. Coons et al. remind us of the many studies suggesting that nearly one woman in five has been coerced into sexual experience before age 13 and demonstrate the effect of such a history on later emotional function. Michael H. Stone, who has published so many careful studies of "borderline" personality disorder, reviews his data in terms of incest. Richard J. Loewenstein suggests that those who cannot talk about what has happened to them may express their pain as somatoform illness. Incest has been the secret trauma lurking behind an enormous fraction of our "untreatable" cases.

Where there is so much secrecy and so many dreadful, life-threatening defenses against a victim's knowledge of his or her personal experience of incest, the reader would expect much discussion of shame. Not so. Only one author (Rosalyn Schultz) mentions shame and in passing, at that. The immense and growing literature on shame (replete as it is with discussions of incest and other forms of sexual abuse) occupies a world far removed from these otherwise excellent authors. Throughout the book one is aware of a bias toward neocortical cognition, toward the alterations in thought patterns found in those who have been abused severely and terrorized by those who hold authority over them. Affect is discussed only in terms of its effect on cognitive function. Yet all of the syndromes discussed here are, at core, responses to overwhelming affective experience.

*Incest-Related Syndromes of Adult Psychopathology* is a breakthrough book that makes it impossible for any reader to ignore the ubiquity of sexual abuse. Brought into accord with the modern study of affect, it offers a new look at the ignored and powerful effects of misguided passion, of sexuality as power over a helpless other.

DONALD L. NATHANSON, M.D.
*Philadelphia, Pa.*

**Adolescence and Puberty,** *edited by John Bancroft and June Machover Reinisch. New York, Oxford University Press, 1990, 279 pp., $39.95.*

This book is one in a series examining issues relating to sex, gender, and reproduction under the editorship of Dr. Reinisch, Director of the Kinsey Institute in Bloomington, Ind. This particular volume is an outgrowth of a symposium on adolescent sexuality and behavior held at the Institute in 1986. A variety of topics were covered: factors influencing the onset of puberty, the emergence of sexuality, the emotional changes associated with adolescence, patterns of sexual behavior, and certain legal aspects of the adolescent role. These are included in the book with a few more current references.

Many of the 26 contributors (mostly M.D.s and Ph.D.s) are careful to distinguish between adolescence and puberty: adolescence is a psychosocial stage of development, whereas puberty is a physical process characterized by hormonal changes and the emergence of secondary sex characteristics. Michael Rutter, Professor of Child Psychiatry at The Institute of Psychiatry in London, one of the book's most outstanding contributors, states that the stereotypical view that adolescence is a time of storm and stress characterized by emotional turmoil and psychic disturbance is incorrect. Most young people pass through adolescence without developing any form of substantial mental disturbance. This view was also held by Erik Erikson, who never intended the term "identity crisis" (also called "adolescent turmoil" by some workers) to be mistaken for mental disorder. It is a normative developmental stage that all adolescents must successfully negotiate before entering adulthood.

Following is a small sampling of some of the many findings about adolescence and puberty reported in the book: 1) Puberty is considered to be early if the first physical signs occur before age 8 years for girls and age 9 for boys and delayed if no physical signs appear before age 13 in girls and age 14 in boys. 2) Adolescent girls who live together develop synchronous menstrual cycles, usually within 3 to 4 months, possibly as a result of pheromonal stimulation. 3) Coital behavior of males is highly hormone dependent, whereas that of females is mainly related to social effects and learning. 4) Almost 20% of teenage girls in the United States have an abortion before reaching 20 years of age. 5) The teenage birthrate is much lower in those parts of the world (e.g., the Flemish-speaking part of Belgium) where there is sex education in the schools and contraceptives are easy to obtain. 6) Providing information to teens about condom use is more likely to result in the prevention of sexually transmitted diseases among adolescents than is telling them not to have sex.

There is a curious omission in this otherwise thorough survey of sexual issues. Except for a tabular notation, masturbation is neither discussed nor indexed. Most psychiatrists regard masturbation as normal for adolescent development and a necessary and important outlet for the control and integration of the sexual drive.

Although it took almost 5 years for the content of the conference to appear in book form, the data are still relevant. There is less attention to AIDS than one might expect if such a conference were to be held today—adolescent girls and boys are now the fastest growing AIDS subgroup in the United States. However, the information about premarital sex, contraception use, age at first coitus, and the role of social pressure on sexual behavior in adolescence is applicable and useful for those who work with persons at risk for AIDS. The consensus appears to be that sex education and condom distribution in the schools are the primary means of combating AIDS, and there is the implicit recommendation that this policy be implemented nationwide without further delay.

This book is so heavily weighted toward sexual issues and reproduction that one might get the impression after reading it that adolescents are driven solely by their raging hormones. As Jean Piaget noted, adolescents are also driven by their concerns for humanitarian issues, religion, ethics, creativity, and abstractions and by their unbounded need to understand the world and their place in it. This is not meant as criticism, however, because the book does not intend to deal with those aspects of the adolescent experience. Rather, it is organized to provide an overview of adolescent sexual behavior and accomplishes that task very well. I highly recommend it to psychiatrists, psychologists, social workers, general physicians, and other workers who provide sex education or counseling to adolescents.

BENJAMIN J. SADOCK, M.D.
*New York, N.Y.*

**Intimate Communications: Erotics and the Study of Culture,** *by Gilbert Herdt and Robert J. Stoller. New York, Columbia University Press, 1990, 458 pp., $40.00.*

The Sambia are a small group of about 2,300 in the highlands of New Guinea who value semen very highly. ("Sambia" is a pseudonym used to protect the identity of the group.) Males pass from an exclusively homosexual behavioral period during which they swallow a lot of semen to a briefer bisexual period and, finally, to exclusive heterosexual relationships. "Semen acquisition is an imperative organizing principle of people's social interaction and sexual behavior. Its magical power does things to people, changing and rearranging them as if it were a generator." *Intimate Communications* is a book about semen and about fellatio, orgasm, masculinity, and femininity. As such it might appeal to cultural psychiatrists, a few outré psychoanalysts, and other connoisseurs of the odd. It also is a book about the acquisition, interpretation, and reporting of behavioral data. As such it may be one of the most important books of the past quarter century.

All psychiatrists have been exposed at some time during their education from college onward to that peculiarly anthropological form of study known as ethnography. Perhaps the best-known work of this genre is Bronislaw Malinowski's irrepressible *Sex and Repression in Savage Society* (1). What is striking about this form of inquiry is the contextual anonymity of the ethnographer.

*Intimate Communications* is a truly revolutionary book in which the authors examine their dissatisfactions with traditional ethnographic discourse. They ask how one can judge an individual's actual perceptions without knowing that individual. Anthropologists often tell us about the strange customs and cultures of exotic peoples, but they fail to consider the whole person as a source of intrapsychic and interpersonal meanings. Moreover, ethnographers never expose themselves, and it is an unseen hand of Science that seems to author their texts. What really happens during field work? Does not the ethnographer's personal or cultural status influence perceptions? And what about the relationship between ethnographers and their informants? Exactly what questions are asked of informants, and what answers are given?

In the 1970s Gilbert Herdt, then a graduate student in anthropology, conducted field work among the Sambia of Papua New Guinea. In 1979, Robert Stoller, a psychoanalyst at the University of California, Los Angeles, visited the field site. *Intimate Communications* is a meticulously detailed, blow-by-blow account of what transpired during interviews with informants. Although the subject matter of the interviews deals with erotics, the book is primarily about the importance of using psychiatric/psychoanalytic techniques to delineate the subjective core of ethnography. "At its center are two principles: the way researchers experience themselves is a vital ingredient of their findings; and, equally, the way informants—subjects, patients, friends—experience themselves shapes what they communicate to us" (p. ix). The result is a new form of discourse, the clinical ethnography, in which the feelings, beliefs, and motives of all the actors are described, interpreted, and compared. The process under examination begins with Herdt's first thoughts about working with the Sambia and ends with a description of the hows and whys of the editing of the book. Thus, the reader is treated to transcriptions of interviews as well to the authors' comments about their own and each other's actions. It is unlike any other book I have ever read.

*Intimate Communications* presents a logical case for the necessary consideration of subjectivity in behavioral sciences. The authors make no appeals to murky forces or ego-id-superego constructs but, rather, focus on the ramifications of individuals' conscious experiences of their institutions, beliefs, and attitudes and on the interplay between inner experience and public behavior. Although the immediate impact of this book will be on anthropology, it may be a harbinger of a pendulum swing in psychiatry. Psychoanalysis outsmarted itself with its overemphasis on psychological reality and hidden meanings, but phenomenology is becoming overbearing with its emphasis on facts (factoids?) and structured instruments. Data that are hard and reliable may also be soft and invalid. When behavior is regarded too subjectively, facts may turn to mush, but mush can masquerade as fact with too exclusive a focus on objectivity. *Intimate Communications* is a heady read, but one can always count on the Sambia to bring the authors to earth.

**Perversions and Near-Perversions in Clinical Practice: New Psychoanalytic Perspectives,** *edited by Gerald I. Fogel, M.D., and Wayne A. Myers, M.D. New Haven, Conn., Yale University Press, 1991, 253 pp., $32.50.*

Like the postulated expansion and contraction of the universe following the initial big bang, psychiatry has had an oscillating interest in and regard for the scientific study of sexuality. In the first brilliant moments of Freudian conception, the vicissitudes of sexuality illuminated this vast expanse of the psychological domain. Human experience was moved by psychobiological instincts, and psychopathology reflected derailments in or conflicts between these erotic forces. Over time and for a variety of not fully appreciated reasons, drive theory began to sputter; concomitantly, competing psychologies of the ego, the self, and object relations developed and came to overshadow their progenitor. With the formal burial of metapsychology and its instinctual creations over the past two decades, interest in sexual experience has shrunk into a state of cold death.

It is in this context that the stirring of new work in the field of sexuality can be appreciated. *Perversions and Near-Perversions in Clinical Practice* represents a fledgling effort in this important area that has been dormant for too long.

It is unfortunate but not surprising that this reawakening requires something as scintillating as perversions to rekindle our interest in the erotic. Perversions are fascinating phenomena, worthy of serious research and study.

This book is a collection of papers, most of which were presented at a conference of the Association for Psychoanalytic Medicine in 1989. Bringing together the likes of Robert Stoller, Arnold Cooper, Louise Kaplan, Otto Kernberg, Jacob Arlow, and Joyce McDougall, Fogel and Myers have succeeded in assembling the major scholars in this field for this work. As such, it gives an excellent survey of the current psychoanalytic thinking about perversions. Unlike other conference-generated works, the chapters here are distinctive yet complementary and the book succeeds in being more than simply the sum of its component parts. Something else: it is fun to read; overall the writing is elegant and captivating.

In reading this book, one quickly notes that there are a handful of shared questions which each author attempts to address and resolve. These uncertainties involve the appropriate definition of perversions, in what manner perversity is related to nonperverse mental functioning, and how transformations can occur between sexual longings and nonsexual functioning (e.g., anxiety, character traits, and patterns of object relations).

Although there is much controversy about the defining characteristics of perversions, the contributors are just about unanimous about the inadequacy of identifying or classifying these phenomena on the basis of manifest behavior. Given an analytic crowd of authors this is not surprising. Stoller and McDougall are clearly the most vocal critics of attempts to "syndromize" perverse actions, condemning such efforts as morally based value judgments that are scientifically indefensible.

Disagreements emerge in attempts to capture the dynamic essence of perversions. Despite nuances of opinion, Cooper, Stoller, and McDougall are all impressed by the repetitive efforts to defend against and repair early (usually preoedipal) trauma. Cooper emphasizes the dehumanizing fantasies used to undo the trauma. Stoller stresses the hate that permeates the erotic script. McDougall highlights the adaptive, relationship-seeking value of perverse action.

In contrast to this consensus, Kernberg sees the hallmark of perversions in what is missing: these people are unable to engage in "the normal range of sexual experience." Using more of a self psychology model, Sheldon Bach also emphasizes signal deficits in symbolic capacity and the capacity for interpersonal involvement. Kaplan concludes that perversions represent conflicts over masculine and feminine identifications and are thus a pathology of gender role identity.

The boundary between the perverse and the nonperverse is a less contentious issue. In keeping with a dynamic framework, most of the authors see perverse mechanisms spanning a continuum from their sublimated use in creativity and play, through episodic nonobligatory sexual fantasies, to routinized enactments that are repeated ad infinitum. The only dissenting opinion is that of Helen Meyers, who asks why some individuals act out their perverse fantasies and others do not. In a brilliant chapter entitled "Perversion in Fantasy and Furtive Enactments," she argues that perversion in fantasy is qualitatively distinct from perversion in action. She then reviews possible psychostructural and conflict-based differences that may explain why one imagines and another acts. The chapter concludes with the advancement of a category of intermediate or furtive enactments between the contained thought and the all-out action.

The question of how preoedipal anxieties can be transformed into conscious sexual urges and how once-conscious sexual longings can be converted into character traits or relational patterns is not so much debated as it is serially voiced throughout the work. In my opinion, answering this question stands as the single most important challenge facing researchers in this field.

Beyond the theoretical controversy that energizes this work, there are rich clinical vignettes presented by Bach, Meyers, and Myers. Although he addresses an admirable topic, Kernberg's chapter "Aggression and Love in the Relationship of the Couple" is burdened by jargon and stereotypes. The last two chapters present analyses of perversion in literary works. In her probing study of the Greek tragedy *The Bacchae,* Ellen Handler Spitz discerns perversion as the near-universal attempt to master paradoxes inherent in the human condition through the use of splitting and doubling. George Stade brings up the rear with a riotously witty dissection of a Mickey Spillane novel that underlines the reciprocal relationship between sexual deviancy and the "straight" world of private detective Mike Hammer.

This is an important work. It will inform newcomers as well as those more experienced with psychosexual disorders. In that it addresses the relationship between sexuality and psychopathology it can be recommended for the larger audience of dynamic clinicians as well. I hope that more works of this kind will follow and that the subject of sexuality will once again captivate our field.

JOHN F. GOTTLIEB, M.D.
*Chicago, Ill.*

**Male Sexual Health,** *by Richard F. Spark, M.D. New York, Consumer Reports Books, 1991, 230 pp., $19.95.*

We psychiatrists talk about, think about, and theorize about sexual desire a lot. So does everyone else. That is because sex is a great (arguably the greatest) shaper of individual lives, civilizations, and species. But psychiatrists have long taken a somewhat proprietary view of sexual feeling and action and particularly in the breakdown of that progression. We staked our claim early in this century. From Freud on there has been a general belief among sex therapists of all persuasions that sexual dysfunction in adults arises from mischief by the unconscious, from the snare laid early by the oedipal configuration. Certainly as late as 1980 there was general consensus among psychiatrists that, for example, male sexual dysfunction was "psychogenic" more than 90% of the time. Before that, we psychiatrists knew all we needed to know about sex, or thought we did. We thought that, in the ideal case, given enough time and a fortunate therapeutic alliance, we could find out and help the individual toward healthier libidinal expression. We gave little thought to vascular, neurogenic, hormonal, or medical/surgical causes. The majority of "sex therapists," most of whom are not psychiatrists, still deliver counseling and therapies with only vague awareness of any causality other than the psychogenic. Most treatment from mental health counselors applies behavioral techniques designed to erase inhibition, hesitation, or too much speed, with little or no regard to physical etiology.

There has been a rapid medicalization of psychiatric training, however, and we have learned more about the physical causes leading to disturbances in male sexual functioning. In addition, the aging population keeps generally healthier by use of medications and surgery, which can reduce libido or the sturdiness of an erection for men of any age. The male population that is growing older is better educated and more likely to get information from popular sources on the formerly most taboo subject. If psychiatrists are *really* to know all about sex they now need help from the outside.

Such important and timely information is available in this book. This volume is one of a series published by Consumer Reports Books, a publishing company with an obvious relationship to the monthly *Consumer Reports,* a magazine devoted to information on available consumer goods. (The idea of "consumer" has taken on broad meanings over time; the "consumed" includes services like loans, insurance, and, for many of us regretfully, medical information and care.) The dispensing of relevant information undeniably has great utility for the patient and the physician.

This book is meant for a mixed audience of intelligent lay and professional readers. The writing is diffuse for the first 50 pages or so with the intention, I assume, of providing the beginner a slow immersion. The more knowledgeable medically trained reader could simply skip these prefatory comments. With chapter 6 there begins a current, simple, clear, and useful description of the neurogenic, vascular, and hormonal factors necessary for potency and the interference with such processes by iatrogenic factors. The chapter on psychological factors serves mainly to remind the reader that although the book's primary focus is on exposition of physiological forces, the conceptually separable factors of psychogenic cause are of great importance. The book goes on to discuss the use and types of penile implants, penile injection, and hormonal pathophysiologies and treatment.

The book presents facts that may have drifted out of focus for the now presbyopic psychiatric practitioner. Those who have some uncertainty in answering the following questions, randomly extracted from the information in *Male Sexual Health,* might benefit from reading this book: 1) What is the relationship of thyroid hormone levels to male erection? 2) Does testosterone always help impotent men? 3) What is the "pelvic steal syndrome" and its relationship to potency? 4) Does prolactin (necessary for milk production) have significance for erection? 5) What is the usefulness in the treatment of impotence of a vacuum constrictor device, yohimbine, vitamin E, phentolamine, papaverine, and zinc? 6) What is the relationship of luteinizing hormone, follicle-stimulating hormone, and gonadotropin-releasing factor to potency and to fertility? and 7) Do these questions have practical clinical relevance?

There may be many clinicians who have complete clarity with regard to such questions. For many others, including myself, whose residency many years ago was mainly devoted to the constantly fascinating and elusive issues of psychodynamics, there is the suspicion that in not knowing enough about the biology of male sexual health I missed important physiological factors over the years—both in patients in treatment and in referrals. Sexual histories must certainly include psychosocial and developmental questions and must now move on to comprehension regarding aging and its impact on hormones, vascular changes, and the differential effects of medication and surgery. This book is a good way to start to come up to speed on these subjects. There is a good set of current references as an additional source of detailed information.

The second edition of this book could use somewhat better illustrations, more diagrams or flow charts (for example, of the hormonal relationships), and a bit tighter editing, particularly in the beginning. These are minor criticisms; psychiatrists and those nonphysicians who practice sex therapies would do well to read this book. Some might be embarrassed if their patients did and they did not.

# Letters to the Editor

## Cognitive Impairment After ECT in Patients With Parkinson's Disease and Psychiatric Illness

SIR: Psychiatric illness in patients with Parkinson's disease is well documented (1, 2). Clinical depression alone is present in approximately 40% of these patients (1, 3, 4). The beneficial effects of ECT on affective and motor symptoms in patients with Parkinson's disease have been noted (2, 5). However, the indications for ECT and its potential adverse effects in patients with this disease are not clear.

We reviewed the medical records of 11 patients (six men and five women) with Parkinson's disease who received ECT for psychiatric illness between 1988 and 1990. They were 52–82 years old (mean=70 years). The diagnosis of Parkinson's disease was made by a neurologist. The duration of the movement disorder was from 1 month to 20 years (mean=5.5 years). Eight patients were taking L-dopa and carbidopa, one was taking trihexyphenidyl, one did not require treatment for mild tremor and bradykinesia, and one refused to take any medication. Also, one patient had received an autologous adrenal medullary transplant for Parkinson's disease. On the basis of *DSM-III-R* criteria, major depression was diagnosed in five patients, major depression with psychotic features in four, depression not otherwise specified and organic hallucinosis in one, and bipolar disorder with manic psychosis symptoms in one. Cognitive deficits were identified in three patients on testing with the WAIS-R, the Wechsler Memory Scale, the Auditory-Verbal Learning Test, and the Wisconsin Card Sorting Test.

All of the patients received three to nine ECTs (mean=5.9) with a Thymatron machine that delivered a pulsed, bidirectional, square-wave stimulus. The electrode placement was unilateral for nine patients, bilateral for one, and initially unilateral and then bilateral for one. Post-ECT delirium complicated the treatment in seven patients and was the major factor in the discontinuation of ECT for six of them. Of the seven patients with post-ECT delirium, five were psychotic and two were cognitively impaired and psychotic before ECT. The post-ECT delirium did not last more than 2 weeks. There were no other medical complications of ECT.

After ECT, there was marked relief from the psychiatric symptoms in three patients and some relief in six. There was no symptomatic change in two patients. Movement symptoms did not change significantly except in two patients: a transient (<6 weeks) decrease in the tremor of one patient and sufficient improvement for decrease in the dose of L-dopa and carbidopa for the other.

Our results support previous reports on the safety and efficacy of using ECT to treat psychiatric symptoms in patients with Parkinson's disease. However, the high incidence of post-ECT delirium that required early termination of treatment raises the possibility of a particular vulnerability to the cognitive side effects of ECT in patients with Parkinson's disease, especially ones with pure cognitive impairment or psychosis or both. Despite this apparent vulnerability, the majority of our patients received beneficial effects from ECT.

## Brief Anabolic Steroid Use and Sustained Behavioral Reaction

SIR: The use of anabolic steroids to enhance the strength, performance, and appearance of athletes continues despite public reports of the destructive properties of these agents. These drugs are widely used in adolescent populations; one study estimated that 7% of male students in the 12th grade had used steroids (1). Common behavioral change in steroid users has included depression, paranoia, obsessional thinking, euphoria, and irritability (2, 3). Clinical reports that have cited these effects have noted that the athletes had used steroids for extended periods, had "stacked" several steroids together, and had used high doses. Casual steroid users may thus consider themselves not at high risk for adverse reactions. I report a case in which brief exposure to a low dose of an anabolic steroid heralded a significant detrimental change in behavior that culminated in armed robbery.

Mr. A, 20 years old, had recently graduated from high school. His premorbid personality, described independently by multiple sources, was "easygoing, polite, with exemplary social behavior." He did not abuse alcohol or other psychoactive drugs. He even volunteered as a lay counselor for delinquent youth.

Mr. A tried out for a semiprofessional football team but fell short of their minimum weight requirement. To increase his weight quickly, he took a 5-week cycle of Equipoise, beginning at 1/2 cc (4 days a week) and increasing 1/2 cc per week. He recalled becoming depressed and irritable. Family and friends, who were unaware of his steroid use, independently noted these changes. He experienced several violent rages during which he destroyed property and once became so angry that he lost consciousness. These changes continued for months after his injections ceased.

Mr. A's behavior became irrational and unpredictable. He was caught racing his motorcycle at speeds up to 160 km per hour. He decided to rob a department store where he had previously worked and disguised himself in army fatigues and a mask. After taking money while holding a nonfunctional pellet pistol, he left the store and waited outside. The police arrived, and when he was caught after a chase on foot, he challenged the officer to shoot him. Clinical examination as well as the MMPI-2 several weeks later revealed no signs of mental pathology. His IQ was in the high normal range.

At trial Mr. A received a 1-year jail sentence, much reduced from the starting point of 3 years in this jurisdiction. The judge ruled that the use of a steroid was a significant mitigating factor and that the use of this agent was distinguished from drugs abused for recreational purposes.

This case illustrates that steroids, even in limited quantities, may induce or perhaps precipitate change in behavior that continues past the period of use. In this patient, who had no prior mental disturbance, use of a steroid was correlated with an unstable emotional plane, bizarre and irrational ideas, and heightened self-confidence. The potential population at risk for steroid-related behavioral reaction may be much broader than bodybuilders and professional athletes.

### Development of Transient Obsessive-Compulsive Symptoms During Treatment With Clozapine

SIR: I present the following two cases because of the interesting and unusual phenomenon that occurred during the course of treatment with clozapine.

Mr. A was a 24-year-old man with a 6-year history of schizophrenia, chronic undifferentiated type. He had not responded to all of the conventional antipsychotic medications. He responded favorably to clozapine, with a 35% drop in his score on the Brief Psychiatric Rating Scale (BPRS) after 12 weeks of treatment.

After he had had about 8–10 weeks of treatment with clozapine, the nurses and therapy aides noticed that Mr. A was checking his belongings over and over again. He was also checking his bedroom door, repeatedly making sure that it was closed properly before going to sleep. His own explanation of these behaviors was, "I know it's crazy, but I can't help it. I have to do it." These symptoms did not cause any significant disruption in his daily routines, and over the next 3 weeks, the symptoms gradually subsided.

Mr. B was a 34-year-old man who had a 15-year history of treatment with very high doses of various antipsychotic medications but continued to remain significantly psychotic, with various positive symptoms as well as dominant negative symptoms. Twelve weeks after he began treatment with clozapine, his BPRS score dropped by 25%.

During the 12th to the 13th week of treatment with clozapine, Mr. B developed an obsession that he was being contaminated with bacteria. He would avoid touching doorknobs and was very skeptical about touching almost anything. He would wash his hands 15 to 20 times a day and spray disinfectant all over his room several times a day. While he seemed to understand the irrationality of this behavior, he could not be talked out of doing these things. The behavior lasted about 1 to 1 1/2 weeks and subsided spontaneously.

Neither of these two patients had any prior history of obsessive-compulsive symptoms. If these symptoms occurred as a result of treatment with clozapine, it would lead to some very interesting speculations about the psychopharmacology of clozapine.

The serotonergic medications such as clomipramine and fluoxetine are very effective in the treatment of obsessive-compulsive disorders. Clozapine is a potent antagonist of serotonin receptors, and pharmacologically it would make sense if blocking off the serotonergic receptors resulted in development of obsessive-compulsive symptoms.

Perhaps etiologically schizophrenia has several subsets and one of them represents a serotonergic neurotransmitter system in the brain where too little serotonin causes obsessive-compulsive symptoms and too much serotonin causes schizophrenic symptoms. It is possible that the primary mechanism of action of clozapine is its antiserotonergic property rather than the token dopamine-blocking activity it exhibits. It is also possible that the 30% of treatment-resistant patients who respond favorably to clozapine represent this subset of schizophrenia. If so, a much less expensive and much less toxic medication such as cyproheptadine, which is also a serotonin antagonist, might play a major role in the treatment of treatment-resistant schizophrenic patients.

### Clozapine-Induced Priapism

SIR: Priapism in patients taking clozapine has not been previously recorded. (The Food and Drug Administration has informed us that they have received three more reports of this problem since our original documentation of this case.) Priapism is defined as a persistent erection, which may be painful but is unrelated to any sexual arousal. Priapism of 4 hours' duration should be considered a urologic emergency.

A variety of drugs have become associated with priapism (1), for example, antipsychotics (thioridazine [2]), antidepressants (trazodone [3], phenelzine [4]), and antihypertensives (prazosin [5]). Various physiologic mechanisms for priapism have been described and may include increased blood flow, decreased outflow, intracorporeal thrombosis, malignant infiltrative processes, or release of cortical inhibition. In addition, it appears that acetylcholine and serotonin may be involved.

Mr. A had been admitted to a residential center at the age of 17 with a diagnosis of profound mental retardation associated with chronic auditory hallucinations. He had been treated for meningococcal meningitis at the age of 6 1/2 months and pneumonia when he was 2 years old. At age 4 he was diagnosed as profoundly mentally retarded, without any focal signs. Prior to his admission to the center, he had taken therapeutic doses of thioridazine, chlorpromazine, fluphenazine, and haloperidol. Despite numerous antipsychotic regimens, he continued to have chronic auditory hallucinations.

Clozapine treatment was started in 1990, when Mr. A was 33 years old, in accordance with a then-published protocol of the Sandoz Company. He was maintained on a regimen of haloperidol, 20 mg/day, in addition to the clozapine. On the 23rd day of the protocol, he was referred for evaluation of fever, rapid heart rate, and elevated blood pressure. A physical examination at the time revealed a blood pressure of 130/80 mm Hg, a pulse of 120 bpm, and an oral temperature of 103 °F. The single significant physical finding was a moderately infected pharynx, without exudate or regional adenopathy. As a urinalysis was requested, his caretaker offhandedly reported that Mr. A had had a persistent penile erection for the previous 48 hours. This finding was confirmed, and the Sandoz Company was notified. They informed us that as of Sept. 28, 1990, there had been no report of priapism associated with the use of clozapine. The patient was referred to the urologic service of a hospital.

In the emergency room at the hospital, Mr. A experienced extreme pain from his erection. He received repeated injections of epinephrine intracorporeally, with transient periods of resolution. A penile cutdown was performed for improved drainage of the corpora cavernosa. A Foley catheter was placed in the bladder, and the patient was admitted to the hospital for observation. Over the following 8 hours, the erection remained despite additional injections of epinephrine. Surgical intervention was then undertaken with a distal corporospongiosal shunt. The patient made an uneventful recovery from this procedure. His penis remained turgid secondary to early fibrosis.

Over the 2 1/2 months of follow-up to date, it has not been documented that this patient is able to develop an erection, which is not unexpected, since it is estimated that about 50% of patients with priapism will become impotent. Following surgery, Mr. A was restarted on haloperidol, 10 mg b.i.d. He continues to have auditory hallucinations.

A review of the literature for drug-related priapism reveals 15 different citations. Clozapine is an atypical antipsychotic without extrapyramidal adverse effects. Its frequent side effects may include hypotension, dizziness, salivation, and sedation. Agranulocytosis is an infrequent but serious side effect. As a precaution, the present protocol of the Sandoz Company requires a weekly blood level determination. Priapism should be added to the list of possible serious side effects.

## Control of Depression With Fluoxetine and Antiseizure Medication in a Brain-Injured Patient

SIR: We have previously reported on the incidence of seizures secondary to the administration of tricyclic antidepressants in patients with brain injuries (1). Because depression can be a frequently disabling problem in this population and often requires drug treatment, nontricyclic drugs such as fluoxetine are increasingly utilized (2). Despite widespread use of fluoxetine, there is little information about the drug's effect on seizure threshold, so it is often considered to be a safe alternative to tricyclics in this regard (3). We report our first case of a possible fluoxetine-precipitated seizure.

Mr. A was a 23-year-old man who had suffered a traumatic brain injury in a motorcycle accident at age 21. He had no history of seizures either before or after his injury. Approximately 30 months after the injury, desipramine was started because of suspected depression. After 2 weeks of desipramine treatment, the patient developed two episodes of generalized seizure activity. The dose of desipramine had been increased to 150 mg/day 1 week before his seizures. The seizures were treated acutely, and the patient was given loading doses of phenytoin. Desipramine was discontinued, since it was suspected as a causative factor for the seizures, and subsequently phenytoin was also discontinued.

Since Mr. A demonstrated improved mood when taking desipramine, and his mood clearly worsened when he stopped taking the drug, a trial of fluoxetine, 20 mg/day, was initiated approximately 2 weeks after the seizure activity. Three weeks after starting fluoxetine, the patient suffered a series of generalized tonic-clonic seizures. He was acutely treated and loading doses of phenytoin were again given. Because his response to fluoxetine had been very positive in terms of mood and participation, the drug was continued along with concurrent anticonvulsant drug treatment, and he experienced no further seizures.

Although it is possible that this patient developed "late" posttraumatic seizures 2 1/2 years after his injury, it is more likely that antidepressant drug treatment, initially with desipramine and later with fluoxetine, lowered his threshold for seizure occurrence. Unfortunately, it is difficult to predict which patients may develop seizures secondary to antidepressant drugs. Fluoxetine may still be less likely to lower seizure threshold than tricyclics, but this impression could be due to a lack of aggregate long-term experience with the drug. Nevertheless, it does appear that in some cases, antidepressant treatment may be maintained when combined with anticonvulsant drugs, as has been demonstrated thus far in this case.

## Automobile Driving by Psychiatric Patients

SIR: Recently I was involved as an expert witness in a malpractice case. A patient with schizophrenia seriously injured two persons when, with his car seemingly out of control, he struck their automobile from behind. A psychiatrist was being sued for malpractice on the grounds, among other things, that he had not advised against driving when specifically asked.

In reviewing five general textbooks of psychiatry, published between 1987 and 1991, I found no mention of driving an automobile. An early publication (1) compared the records of 271 psychiatric patients with those of 687,228 persons in the same driving environment who were not psychiatric patients. Patients with personality disorders and psychoneuroses had higher accident rates than the comparison population. Those with schizophrenic disorders had rates similar to those of the comparison group. A recent review article (2) found no evidence that schizophrenia increased the number of road traffic accidents, either in the United States or in Denmark. Manic disorders might be potentially dangerous, but adequate data were lacking. Depression might contribute to accidents by virtue of slowed responses or suicidal intent; however, only 1.7% of fatal accidents were attributed to suicide. The clearest indication of a psychiatric disorder impairing driving involved a patient with Alzheimer's disease. Among 522 consecutive patients with dementia, 333 were licensed to drive at the time of onset of their dementia. However, the median length of time during which they drove after onset was almost 29 months. Most important, 21 of the 93 patients still driving at the time of the survey had been involved in motor vehicle accidents within the previous 6 months (3).

The absence of any guidelines in formal psychiatric texts and the paucity of the scattered literature suggest that the psychiatric profession feels little responsibility to determine fitness to drive. Such an attitude might be justified by the fact that it is really those persons closest to patients who might be most aware of their limitations. The decision about what advice to offer then becomes a matter of common sense. Some cases are easy; any lay person would be reluctant to ride in a vehicle driven by a wildly hallucinating person. The more difficult cases might be those in which the patient has attained some degree of remission. It might still be prudent to err on the side of conservatism. Operating a motor vehicle is deemed by most people as a right to be abrogated only under the most stringent circumstances. As long as psychiatric patients who might be impaired can freely obtain licenses, psychiatrists can only offer advice. In flagrant cases such advice might be volunteered. When one is asked directly, the pros and cons of driving should be discussed until some conclusion is reached. The issue can no longer be evaded.

## Experiences in Beginning Therapy

SIR: My group of students in their second postgraduate year is currently experiencing the anxieties and rewards of beginning therapy with a variety of patients in such diverse settings as a locked unit, an open unit, an emergency service, and office visits. I have become interested in the dynamics of such first meetings and the expectations and emotions that the therapist brings into the session. I am soliciting anecdotal accounts of first encounters with patients, with the intention of publishing an anthology, tentatively entitled *At the Very Beginning.* Contributions from all disciplines are welcome. Manuscripts should be double-spaced and range in length from 2 to 20 pages.

## "Pseudohypermnesia": A Conscious Effort to Avoid Telling the Truth

SIR: A felon endlessly added new details to his allegations. He insisted that no one could ever know the whole story and that until the whole story was known he could never be found guilty. The added facts were, by and large, impossible to verify. His presentation gave the clear feeling of confabulation, but it was not an unconscious filling in with imagined or untrue experiences; rather, it was an obvious and designed behavior.

We propose the term "pseudohypermnesia" to describe this phenomenon of intentionally and consciously exaggerating the degree of retention and recall. It is meant to be different from paramnesia (falsification of memory by distortion of recall) or retrospective falsification (adding false memories to true memory) because the added memories may not be entirely false but just detractors. In pseudohypermnesia the memories may or may not be true, and the pseudohypermnesic person will not resist efforts to verify his story; his willingness is partially based on his assumption that we do not have the time, interest, or energy to make such an investigation. Furthermore, he knows that witnesses cannot be located, and so his story remains free from attack. And ultimately he can always add another variable.

This is not the memory equivalent of a neologism. The memories are not necessarily created by the person, although there may be some effort at retrospective data forgery to fortify his allegations.

Obviously, this reflects deficits in insight, but it is not automatically an impaired judgment, because such behavior has probably worked in prior situations and so has reinforced itself. It does contain some narcissistic and antisocial personality qualities.

Studies of hypermnesia suggest that memory and recall are both vulnerable to the person's understanding of the consequences of his recall (1–5). Recall can even be faked on formal neuropsychological testing. Hypnosis offers no significant increase in valid recall; it appears limited to widening the person's criteria for what he declares to be a valid memory. There is some question about the order of testing and interviewing. Rey's test for malingering may have more clinical value if it is used before other testing and interviewing occurs, so subjects are not sensitized to its intent. On the other hand, there is evidence that repeated attempts at recall with eyewitnesses to events may foster accurate hypermnesia; the difference between hypermnesia and pseudohypermnesia is that the additional memories in the former increase the accuracy of recall, whereas in the latter, repeated efforts at questioning the subject may provide a greater chance that credibility will be further diluted.

In summary, we propose the term "pseudohypermnesia" to mean an unbelievable and extraordinary amount of "precise" recall, with an endless list of possible details, excuses, and variables with respect to why or how an event occurred. Usually, pseudohypermnesia occurs when the person wants to mislead the listener.

### Sequelae of Denied Abortion

SIR: "The Psychological Sequelae of Therapeutic Abortion—Denied and Completed" by Paul K.B. Dagg, M.D. (1) is excellent. We would like to underline the sequelae of denied abortion, as political and public attention to this issue continues to increase. We were struck by the cases of two patients who recently came to our small general psychiatry inpatient unit in a state hospital facility within just 1 month's time.

Ms. A, a 23-year-old single woman who abused cocaine and heroin, was sent involuntarily to the state hospital from a general hospital that did not have a psychiatric unit. She had presented to the hospital "binging on cocaine for a month trying to kill the baby" and saying she would kill herself if she did not get an abortion. The abortion was performed, and the patient was sent to our hospital for further evaluation. She denied having had psychiatric treatment or formal detoxification in the past and denied ever being suicidal, saying she had only threatened suicide to obtain the abortion. She also denied being depressed. At the end of a week's hospitalization, after further history had been obtained from her family, her boyfriend, and the previous hospital, it was determined that she was not then a danger to herself or others and, at her insistence, she was discharged to outpatient counseling, Narcotics Anonymous, and gynecologic follow-up.

Ms. B, a 28-year-old divorced woman, was transferred involuntarily on physicians' certificates from a local hospital emergency room. She said she would hurt herself or get her boyfriend (not the father of the fetus) drunk so he would beat her up, in an attempt to kill the fetus. She worried that the Department of Social Services would not process her "paperwork" in time for her to obtain a legal abortion. She reported no past psychiatric hospitalizations. She noted that she already had two young sons and was in a custody battle with her parents over them. She also cited severe back pain, getting a new job, and moving in with her new boyfriend as other reasons for wanting an abortion. She insisted that a baby would "ruin" her life. She felt that no one was willing to help. The patient soon began denying thoughts of hurting herself, saying she wanted to leave and take care of her problems. She was released by an administrative law judge in a hearing after 4 days. Her social services worker was contacted, and an outpatient clinic appointment was made.

Such cases humanize the abortion discussion. We support APA's strong prochoice position that "any decision on abortion should be strictly between a woman and her physician" (2). A woman who desperately wants an abortion will get one. Some 40% of women who are denied abortions receive them elsewhere (1). Dr. Dagg also describes as "alarming" reported rates of "spontaneous" abortion in this population, when spontaneous miscarriage should be rare. We are again concerned that restrictive legislation on this issue, as on others, most affects those who are already disadvantaged, those who already have fewer choices. Last, but by no means least, we were struck by the findings that few children of unwanted pregnancies are adopted out, and the remaining children suffer "long-lasting, broadly based, negative effects." We are gravely concerned for the children of unwanted pregnancies and grimly expect to see them in our clinics and hospitals through the years.

### Factors Affecting Patient Dropout Rates

SIR: The study on patient dropout rates by William H. Sledge, M.D., and colleagues (1) warrants comment because of methodological problems and the possible misuse of their conclusions by regulators pursuing fiscal restriction in psychiatric practice. The authors' results would appear to support the hypothesis that time-limited psychotherapy has the intrinsic advantage of a lower dropout rate than approaches lacking a pre-set termination date, suggesting greater cost-effectiveness without regard to patient selection and outcome measures.

Several easily measured variables not mentioned in the report that could have accounted for the differential dropout rates include 1) length of the assessment phase preceding referral, 2) dropout rates during or after assessment but before starting treatment, 3) transfers to a different clinician for treatment after the assessment, 4) frequency (as opposed to length) of therapy, 5) the therapist's professional discipline, 6) type of sex pairing, and 7) prior dropout history. Differential outcome measures, such as recidivism rates, are also relevant. In the literature on treatment dropouts there is evidence to suggest that an evaluation phase of more than one session tends to decrease the likelihood of dropping out of treatment (2), transferring patients to new clinicians for therapy increases the likelihood of dropouts (3), higher frequency of sessions is associated with remaining in treatment (4), professional affiliation and sex matching can be related to therapist "holding power" (4), and previous dropouts from treatment are more likely to drop out again (5).

If, for example, patients selected for time-limited psychotherapy in the study by Dr. Sledge and associates happened to have a longer evaluation phase than the other groups (say, in order to determine suitability, assess motivation, and set a focus), it is possible not only that an extended evaluation increased the likelihood of their staying in treatment but also that any attrition was more likely to have occurred before treatment began. Independent of diagnosis, patients selected for time-limited psychotherapy might have been considered more suitable, motivated, or attractive therapy candidates who made better matches and thus may have been less likely to be transferred to another clinician after assessment. (Differential transfer rates provide a window on the issue of selection bias. Selection factors are critical, as illustrated in the review by Reder and Tyson, cited by Dr. Sledge and associates, in which patients in brief psychotherapy had a lower dropout rate than patients in long-term psychotherapy, but the lowest dropout rate was among patients in psychoanalytic treatment.) In addition, the brief psychotherapy patients on average had fewer sessions than the time-limited psychotherapy patients, suggesting that the latter did, in fact, meet more frequently.

It is noteworthy that some of the therapists in the study were in a didactic seminar on the time-limited method, which was being taught and developed as the clinic standard for brief psychotherapy. A "halo effect" would have been difficult to avoid. By analogy, patients have been known to dream more when their therapists participate in a dream seminar, even though this fact is not voiced to the patients, who become "better patients" by dreaming more, perhaps because dream material is elicited more or because of other, nonverbal cues from the freshly interested therapists.

While the conclusions of Dr. Sledge and associates may still be corroborated upon a fuller consideration of variables, the scientific and therapeutic basis for recommending a time-limited approach over other therapies for patients in general has not been clearly established. This point is worth emphasizing at a time when, as in Massachusetts, some public policy makers, regulators, and insurers seek to restrict the range of treatment options.

## Dr. Sledge and Associates Reply

Sir: Dr. Good's letter addresses some important considerations. We examined some of the suggested and alternative hypotheses that he mentions before we wrote our report, and we will simply say what we can about them at this point. 1) There was no difference in the length of the assessment phase or the number of assessment interviews between dropouts and those who remained or among the three different types of psychotherapy reported in our article. 2) Patients who dropped out before treatment began were not included in our report. 3) There was no difference among the three types of treatment and the transfer to a different clinician from the evaluating clinician, and there was no statistically significant difference between dropouts and those who remained on transfer from a different evaluating clinician. 4) We did not analyze the frequency of therapy because almost every treatment involved weekly sessions only. 5) As noted in the article, there were no statistically significant differences in the professional disciplines of therapists by type of therapy. 6) We did not examine the type of sex pairing. It is certainly a reasonable and interesting hypothesis, but differences in both same and different sex pairs could not account for the robustness of our finding. 7) We do not have data to address the point on prior dropout history. However, it should be remembered that the patients were relatively new to psychiatric treatment, and all had been out of the clinic in the 2 years before the study. Again, it is highly unlikely that prior dropout history could account for the robust findings we reported.

Dr. Good makes the point that there could be a halo effect secondary to the acquisition of a new skill and knowledge from an enthusiastic staff. This is a possibility; and, of course, it is the reason we indicated in the article that some staff members had recently learned the Mann method. But many staff members also were learning to do brief treatment not based on Mann's technique. However, as we reported, brief treatment without the Mann technique had twice the dropout rate of brief treatment with the Mann technique. Dr. Good also notes the possibility of a selection bias. We think that it is indeed possible that some subtle selection bias occurred, but not necessarily along the lines he suggests, namely, that the time-limited patients were more "suitable, motivated, or attractive therapy candidates."

As indicated in the article, our study was archival and retrospective and, therefore, subject to the possible influence of uncontrolled biases. Given that fact, it would be highly inappropriate for policies of a public or private nature to be based exclusively on our report. On the other hand, the finding was very robust, and it would be highly inappropriate to ignore it. A useful response to the study would be to do a prospective investigation of the issues.

## The Opioid System and the Placebo Response

Sir: We were interested in two articles published recently regarding the placebo response in patients receiving antidepressants (1, 2). The authors highlighted possible different types of placebo response, contrasting rapid improvement to a more gradual process. The latter type of placebo response has to be distinguished from spontaneous remission. The authors mentioned that the dramatic onset of abrupt and sometimes transient mood improvement suggests that some endogenous substance might be involved. Their candidate was phenylethylamine (1). It is possible that the endogenous opioid system may also be involved (3, 4). A variety of endogenous and exogenous opioid compounds have been shown to elevate mood (5). In our studies dealing with alcoholic withdrawal states (3, 4), we initially administered placebo and used an active substance only after the placebo trial had been completed. This paradigm seems to have been similar to the one used by Dr. Quitkin and associates (1).

## Meaning of Refractory Depression

SIR: Richard Guscott, M.D., and Paul Grof, M.D., Ph.D. (1) provided an excellent review on the clinical meaning of refractory depression. They noted that "suggestive evidence points to the coexistence of a medical or nondepressive psychiatric disorder as a problem in depressed patients who are considered refractory to treatment." In fact, there is a substantial body of data indicating that persons with secondary depression are less likely to achieve recovery than persons with primary depression (2). Although the primary/secondary diagnostic scheme has never achieved popularity, it remains one of the best validated (3).

Drs. Guscott and Grof failed to note that the presence of an accompanying personality disorder also has substantial impact on response to treatment (4). It is important to point out these associations, since clinicians need to understand which variables have an impact on recovery.

DONALD W. BLACK, M.D.
*Iowa City, Iowa*

SIR: The article by Dr. Guscott and Dr. Grof was excellent. I would like to highlight and ask them for clarification of a point they made that resonated with my own clinical experience. Concerning serum monitoring of antidepressants, they noted, "There is virtually no evidence to demonstrate that the use of serum monitoring in routine clinical practice improves therapeutic outcome. We also suspect that in many clinical situations the monitoring of tricyclic antidepressant levels can lead to inappropriate clinical decisions. We have observed many situations where patients have been kept on subtherapeutic doses because of levels above the 'therapeutic' range" (p. 698).

In our center, especially of late, there seem to have been many values in the 150–250 ng/ml range with therapeutic doses of nortriptyline. The therapeutic range is reported to be 50–150 ng/ml. Concerned about laboratory error, we got a confirmatory value from a second laboratory in a recent case. Although these two values were close—175.6 and 169.0 ng/ml—they were both quite different from the value of 235.1 ng/ml reported 3 days earlier when the patient was taking the same dose, 100 mg at bedtime. The patient's ECG was normal.

Generally, I have had levels ascertained 3–4 weeks into treatment, when an optimal response has not yet been achieved, with the rationale of "seeing where things stand," especially concerning the further increase of antidepressant dosage. When the level has been greater than 150 ng/ml, I have been torn between lowering the dose (recently, in one instance I did that and the patient experienced a clinical worsening of depression) or leaving it as is (done with four patients), noting in the chart concerns about the validity of the laboratory values and the absence of clinical toxicity. I have not had the "guts" to increase the dose further in the face of an already "high" level.

Are we ascertaining antidepressant serum levels too routinely or too soon? I would appreciate the comments of Drs. Guscott and Grof.

## Dr. Guscott Replies

SIR: Dr. Black makes two observations on our review that raise serious and challenging scientific and clinical issues. First, he points out that the category of "secondary" depression is much more validated than we have implied. Clearly, there is good evidence that patients with secondary depression have a poorer treatment response than those with "primary" depression. His own research clearly supports this position (1). His point is well made. His own research also points to inadequate treatment of secondary depression as a major clinical problem.

However, there appears to be continuing controversy about the validity of the distinction, reflected in the failure of *DSM-III-R* to recognize the distinction. We would conservatively share the view of others that the separation of primary from secondary depression, although controversial, is required for pragmatic reasons (2).

Dr. Black further states that we failed to note the substantial impact of a personality disorder on response to treatment. In fact, in our review we stated, in agreement with Dr. Black, that the "coexistence of a medical or nondepressive psychiatric disorder" is a factor in response to treatment. The extent of this impact on treatment response, we think, is unclear. The NIMH collaborative study cited by Dr. Black pointed to mixed results. The researchers' own interpretation of the results was that although patients with personality disorder had a less favorable result, this depended upon the outcome measures used. For example, there was no difference in outcome on mean Hamilton Rating Scale for Depression scores, work functioning measures, or the HSCL-90 depression scale. Social functioning was less improved in the personality disorder group. However, the log linear analyses of Personality Disorder Group by Treatment by Recovery revealed that "patients with personality disorders improved" but were "more likely to have residual symptoms of depression" (3). In our view, this means clinically that we must have good baseline measures of both symptoms and functioning, with the appropriate targeting of our interventions.

Dr. Storch raises a challenging clinical question with regard to serum antidepressant monitoring. The question of "too routinely or too soon," in our view, depends on the clinical context (and in some areas, perhaps the legal context!). Our own position is that levels themselves are only guides and do not indicate either toxicity or the "upper limit," similar to digoxin levels. Only a clinical assessment can determine toxicity. In my own practice, a high level (above the "therapeutic range") in the absence of major side effects would not be a contraindication for increasing the dose.

Although others, notably Preskorn and Jerkovich (4, 5), have made excellent arguments for the clinical use of serum monitoring, we remain concerned that some clinicians continue to treat the "levels" rather than the patient.

## Performance Anxiety

Sir: As a professional musician and a psychiatrist frequently consulted by performing artists afflicted by stage fright, I read with interest the article on performance anxiety by Duncan B. Clark, Ph.D., M.D., and W. Stewart Agras, M.D. (1). I doubt, however, that the method used to assess the level of anxiety in the subjects adequately replicates a real-life performance experience. In addition, I wish to ask the authors what criteria they used to determine a "better" or "worse" musical performance and those for selecting the raters.

My own therapeutic approach to the problem of stage fright is eclectic and includes an insight-oriented as well as a cognitive aspect. Except for the beginning phase of treatment, where β blockers can be of real temporary help, I agree with the authors that minor tranquilizers should be avoided.

I highly recommend the reading of *The Inner Game of Music* (2), which provides a useful self-help guide to many of my patients.

PHILIPPE E. CHANEL, M.D.
*Washington, D.C.*

## Dr. Clark Replies

Sir: I thank Dr. Chanel for his interest in our work. With regard to the method used to assess performance anxiety, the laboratory evaluation did include a live performance experience. We believed that it was methodologically important for the performance setting to be the same for every subject, and identical before and after treatment. Therefore, it was not feasible to use performance situations that the subjects would naturally encounter outside the laboratory. In the laboratory performances before treatment, subjects reported a mean subjective anxiety level of 7.1 (range=2–10) and had a mean increase in heart rate of 31.4 bpm (SD=16.2). Informally, subjects indicated that the setting was similar to an audition or juried performance. While this was not identical to each subject's unique naturally occurring performance situations, we believe this method to be valid.

These laboratory performances were audiotaped and were presented in random order to experimentally blind raters. The raters were asked to compare two performances of the same piece by each subject without knowing which was before and which was after treatment. They then rated the second of the two performances on a scale ranging from "much worse" to "much better." When the subject was performing a classical piece, a musical score was provided to the rater. The diverse nature of the musical performances, which included a jazz drum improvisation, an original country western song with guitar, and an operatic aria, precluded the possibility of a uniformly applied objective criterion such as an error count. The raters were undergraduate music students with extensive performance experience.

While insight-oriented psychotherapy may be helpful for some musicians, this method has not been demonstrated to be useful for performance anxiety. A review of the literature (1) shows that, aside from case reports, the use of psychodynamic psychotherapy for performance anxiety in musicians has not been studied. The most relevant controlled study was on speech anxiety and showed psychodynamic psychotherapy to be equivalent to an attention placebo (2). On the other hand, our study adds to a growing body of research documenting the effectiveness of cognitive-behavior therapy for performance anxiety in musicians.

## Factors in Homelessness Among Psychiatric Patients

Sɪʀ: In a recent article (1), Ezra S. Susser, M.D., M.P.H., and associates extended their important research (2) elucidating childhood antecedents of adult homelessness among psychiatric patients. They found an impressively high rate of foster home placement in childhood among patients in a state hospital who had ever been homeless, ranging from 17% to 22%, compared with 2% for the never-homeless patients. Less effective kin support is the mechanism the authors hypothesized as the link between foster care in childhood and adult homelessness. One could perhaps say that many of these individuals thought of themselves as homeless even in childhood, long before they became chronically mentally ill. More than two-thirds of the authors' state hospital sample, presumably equally ill, had never been homeless. Clearly, homelessness follows a complex series of events, and the presence of a serious psychiatric disorder is only one of many factors.

It has been fashionable to blame deinstitutionalization for the increase in homelessness in the 1980s, even though during the peak years of the depopulation of state mental hospitals, beginning in 1955, homelessness was not a serious problem. The theory that homelessness is caused by mental illness and mental health policy has been embraced by our field despite the lack of evidence to support such a position (3).

This view, fortunately, is gradually shifting. Increasingly, advocates for the homeless and even some mental health professionals cite multiple factors as the causes of homelessness: high unemployment, limited education and skills, the low wages of many workers, increased numbers of single-parent families, loss of family networks, disappearing low-income housing stock, a diminution in the availability and generosity of social welfare benefits, physical disabilities including AIDS, and the complex relation between substance use and all of these other stressors.

The mental health system has a role to play in addressing homelessness, but that role is limited to certain specific interventions, such as the one proposed by Dr. Susser and associates, which we have the resources and expertise to implement. We should not be too eager to claim responsibility, or accept blame, for the increasing public squalor of American life.

## The Mind-Body Problem

Sɪʀ: Aviel Goodman, M.D., in his article on organic unity theory (1), provided a conceptual framework for psychiatry that has a basic flaw. To say that "the conventional dichotomy between physical (organic) and mental (functional) is linguistic/conceptual rather than inherent in nature" (p. 553) is to beg the question, as it sets up another dualism. A monistic stance is needed (the middle column of Dr. Goodman's figure 1) which places dualistic terms (the right-hand column) and monistic terms (the left-hand column) on a continuum, in order not to deny either, which would cause the perspective to regress to dualism.

Moreover, such terms must link dualistic and monistic terms in an asymmetric fashion. Dualistic terms establish a symmetry between opposite categories from the perspective of a supraordinate category. Monistic terms establish a continuity between opposite categories that is latently dualistic and symmetric because of its reversibility when viewed from the perspective of the supraordinate category, which is equivalent to a perspective within the continuum in which forward and backward are interchangeable. If, and only if, this continuum is asymmetric can monism be liberated from latent dualism and become a "psychophysical term," an "embodiment" of a dualistic term, or an "ensoulment" of a monistic term with dualistic subjectivity.

For example, absolute irreversibility of time (making its appearance with quantum mechanics) seems to "ensoul" physical reality. It "embodies" consciousness by asymmetrically connecting the categories of past and future, from the perspective of the present moment, wherein an ordered or timeless mode of knowing (dualism) applicable to the subjectively experienced past in contrast to the future, and a timeful, nonhierarchical mode of knowing (monism) applicable equally to all times, coincide (Richard P. Goldwater, unpublished manuscript).

All psychiatric disorders can be completely described as failures of integration of the two modes of knowing (Goldwater, unpublished manuscript). Severe lesions in categorical thinking produce schizophrenia-like syndromes, and severe lesions in monistic thought produce affective (or categorical) disorders. The neuroses can be understood as failures of integration of dualism and monism, incarnate in the child's perspective as Mom and her relationship with Dad in the Oedipus complex. Problems with "separation-individuation" are more clearly understood when separation is seen as dualistic and individuation as the monistic complement.

Both biological and psychological psychiatry share a prejudice against dualism and therefore against "events, states, and processes . . . to which both mental and physical concepts refer" (p. 558), because such things require a monism that incorporates dualism rather than a monism that perpetuates it.

JOHN R. JACOBS, M.D.
*Glen Oaks, N.Y.*

Sɪʀ: The respectable attempts to unify the mental and the physical (Carnap's theses of unified science, Feigl's identity theory, etc.) suffer distortions in the hands of Dr. Goodman. For example, he says, "Physical terms are associated with statements that are intersubjectively confirmable, whereas mental terms are associated with statements that are only subjectively confirmable" (p. 556). Compare the sharply contrasting view of Feigl (1), whom Dr. Goodman quotes approvingly: "The decision to rule out as scientifically meaningless statements which are not even indirectly confirmable . . . reflects the conviction that whatever is subjectively verifiable is in principle also intersubjectively confirmable." This is a cornerstone of "identity" philosophers' view, since they regard the language of objective science as the only meaningful language. Carnap (2) was the first to point out that there cannot be a subjective term in intersubjective language which could not be explicated behaviorally. A child learns to say "I am tired" after hearing the parents saying it because they notice behavioral signs of fatigue, or the situation calls for such an expectation.

Dr. Goodman says, "There exist 'pure psychophysical events' that the subject and the observer experience differently . . . and that they designate with different classes of concepts" (p. 557). But any scientifically respectable concept must have intersubjective criteria of application and thus be, according to Dr. Goodman, physical.

The practical consequences of Dr. Goodman's position are similar to those of dualism. He sees a possibility of formulating a psychiatric diagnostic system in physical concepts, in mental (subjective) concepts, or in a combination of the two, but the last "is likely to lead to confusion on logical as well as factual levels" (p. 562). However, the trend of psychiatry seems to be to integrate the subjective, behavioral, and neurophysiological data. That has also been the philosophical background of the attempt of one of us (F.K.) to integrate psychotherapy (3). Does not Dr. Goodman himself say, "The identity theory postulates that the referent of a mental term is identical to the referent of a corresponding physical term" (p. 557)? And Feigl concludes, "Private, immediate experience as such is only the raw material, not the real subject-matter of science."

In practice, Dr. Goodman's position leads to compartmentalization of psychological and psychiatric concepts. He criticizes Engel for talking about experience and behavior at the same time and says, "Experience is a mental concept, representing direct, first-order knowledge . . . that is confirmable only subjectively; behavior is a physical concept" (p. 558). Let us assume that a certain task cannot be successfully accomplished unless one understands and remembers the appropriate instructions. We then conclude that a person who accomplishes this task has gained that experience, without asking about that person's subjective experience. Then "experience" is a behavioral concept which can be coordinated with a subjective concept.

SIR: Dr. Goodman presents a clear and detailed treatment of the mind-body problem that is informed by recent work in the philosophy of science and applicable to general psychiatry. His position, in summary, is 1) that the current biopsychosocial paradigm, as evolved from general systems theory, ultimately entails a dualistic account of mind-brain relationships, 2) that mental-physical (mind-body) identity theory, as developed in the philosophical literature, avoids "dualistic fallacies" (p. 561), and 3) that a synthesis of the biopsychosocial model and mental-physical identity theory resolves the mind-body problem and obviates misleading biological-psychosocial dichotomies. The argument includes a concise review of the philosophical difficulties in dualism, e.g., "if a mental force that could influence physical entities and processes were postulated, it would then by definition also be a physical force, which would not be consistent with dualism" (p. 555).

Mental-physical identity theory holds that the seemingly radical difference between the mental and the physical is an artifact of point of view and of differing conceptual systems: "the mental and the physical are not two realms or concomitant types of events but one reality represented in two conceptual systems" (p. 557). The difference is epistemological, not ontological.

Dr. Goodman argues that the standard view of a systems hierarchy can be modified to preserve the epistemological distinction between the intersubjective, neurophysiological realm and the subjective, experiential realm without requiring either reductionism or dualism. An intriguing aspect of Dr. Goodman's thesis is that mental systems may be conceptualized in levels of organization that are not restricted to those coextensive with brain activity. During interpersonal communication, for example, there clearly exists a meaning and information exchange process that is superordinate to the mental processes of a single brain. He states, "Conceptualization of this possibility—of levels of organization of mental systems other than the human nervous system—is limited by the difficulty in attributing phenomenal experience to levels of organization designated by subpersonal or suprapersonal terms and in imagining what other forms of mental properties there might be at these levels" (p. 559). Indeed, psychiatry already contains a rich store of data—from study of phenomena such as unconscious fantasy, ego psychology and object relations, transference/countertransference, group process, and family dynamics—that could guide investigation of subpersonal and suprapersonal mental properties.

I would take issue with Dr. Goodman's statement that the biopsychosocial model's provision for the mind-body problem is "flawed" (p. 553). The biopsychosocial model, through its conceptual relationship to general systems theory, may have philosophical implications but is not, strictly speaking, a philosophical theory; it is a general conceptual framework for empirical activity not designed to resolve philosophical issues such as the mind-body problem. Mental-physical identity theory, on the other hand, explicitly postulates a general, ontological account of events and reality.

Dr. Goodman's organic unity theory is indeed a "synthesis" (p. 558) of the biopsychosocial model and the more philosophical mental-physical identity theory, not a correction of a flaw in the former by use of the latter. The article stands as an example of rigorous philosophical thought being used to clarify fundamental tensions in our field and extend the horizons of research.

STEPHEN R. SETTERBERG, M.D.
*New York, N.Y.*

## Dr. Goodman Replies

SIR: I am grateful to Drs. Jacobs, Knobloch, Hahn, and Setterberg for their interest in my article and for the thoughtful and thought-provoking feedback they have offered. The letters from Dr. Jacobs and Drs. Knobloch and Hahn have been particularly helpful in calling to my attention a flaw in the presentation of my position. Both correctly point out that redefinition of the mental-physical dichotomy as linguistic/conceptual rather than inherent in nature, while intended only to describe the culturally prevalent pattern of linguistic/conceptual practice, in effect perpetuates dualism in one form or another: either a dualism between mental reality and physical reality (if reality which is apprehended conceptually is the only reality that we consider real) or a dualism between what is apprehended conceptually as real and the reality that exists apart from our conceptual apprehensions. In the context of my formulation, the claim that "pure psychophysical events" are real would presuppose the latter form of dualism; the claim that they are not would entail the former.

Mental terms and physical terms differ in significant ways and can be segregated to form classes that reflect these differences. The linguistic/conceptual realm is, however, best represented not as two or more discrete networks but as one continuous network (1, 2). What then constitutes the difference between mental and physical areas within this network? The distinction between statements that are intersubjectively confirmable and those that are confirmable only subjectively does not withstand scrutiny, since all language is learned intersubjectively and must continue to have some degree of intersubjective confirmability in order to function as a means of communication. Intersubjective confirmability is in any case not a property of a statement in itself; it is a property of a statement in a particular context and depends on what is accepted as constituting evidence for confirmation and on the ability of the evaluator to perceive and assess that kind of evidence. At this time, my best formulation is that the difference between mental and physical terms can be characterized according to the type and complexity of the collateral information required to accept a given event as confirmatory evidence, the knowledge and abilities necessary to perceive and utilize the collateral information, and the degree of resistance to changing a judgment about whether an event constitutes confirmatory evidence (which is related to the collateral information factors). This idea parallels Mary Hesse's thesis (3, 4) that observational and theoretical terms differ only in their degree of entrenchment and the conclusion of van Brakel and Geurts (5) that literal and metaphorical meanings differ only in their degree of social fixity.

While I agree with the criticism noted in the preceding paragraphs and appreciate the stimulus to improve my formulation, there are a number of points in the letters from Dr. Jacobs and Drs. Knobloch and Hahn that I have difficulty accepting or perhaps do not correctly understand. In the first paragraph of his letter, Dr. Jacobs identifies the right-hand column in my diagram (which represents the conceptual network of mental terms) as "dualistic terms" and the left-hand column (which represents the conceptual network of physical terms) as "monistic terms." There is no explanation of why mental terms should be considered dualistic while physical terms are considered monistic. Meanwhile, this suggestion does not eliminate the linguistic mental-physical dualism that characterized my initial formulation; it merely relabels it—and with terms that seem to convey less relevant information than do the original terms. The second paragraph may express some important ideas, but I find it difficult to understand. It is not clear which terms "must link dualistic and monistic terms in an asymmetric fashion," nor is it clear how this linkage contrasts with the symmetrical relationship presumably established by dualistic terms. The final sentence is particularly confusing. How can monism at the same time be a "psychophysical term," "an 'embodiment' of a dualistic term," and "an 'ensoulment' of a monistic term with dualistic subjectivity"? Discussion in the third paragraph presupposes conceptual relationships that are not readily apparent and could benefit from clarification, as with the following questions: How are the terms "ordered" and "timeless" interchangeable in describing a mode of knowing? What is the connection between dualism and the ordered or timeless mode of knowing? How is "ordered" opposite to "absolute irreversibility of time"? (the latter phrase is more clearly in opposition to the idea of a time-space continuum, which is an aspect of relativity theory). And what is the relationship between the dualism-monism dichotomy and the timeless-time irreversibility dichotomy? The statement with which the fourth paragraph begins—"All psychiatric disorders can be completely described as failures of integration of the two modes of knowing"—is quite an ambitious claim to make without any substantiation. It neglects the physiological, behavioral, interpersonal, and psychodynamic aspects that are also involved in a complete description of psychiatric disorders, and it seems to mistake symptom for cause. The final paragraph of the letter cites part of a sentence from my article and associates it with dualism. The original sentence reads, "In between, in parentheses, are terms which represent systems of events, states, and processes (either postulated or imaginary, but in any case indemonstrable) to which both mental and physical concepts refer" (p. 558). It is clearly monistic with respect to the events, states, and processes, so the statement that a "prejudice against dualism" is "therefore against 'events, states, and processes . . . to which both mental and physical concepts refer'" does not make sense. In fact, the sentence is referring to the middle column of my diagram, which Dr. Jacobs in his first paragraph identifies with a monistic stance.

The letter from Drs. Knobloch and Hahn claims in its first paragraph that "respectable attempts to unify the mental and the physical . . . suffer distortions in the hands of Dr. Goodman" and offers as evidence statements of Feigl and Carnap which contradict my formulation of mental-physical identity theory. As I have acknowledged above, the proposition that the distinction between mental and physical terms depends on intersubjective confirmability (which I borrowed from Feigl) is incorrect. I do not agree, however, with the claim that "the only meaningful language [is] the language of objective science" or with Carnap's point that "there cannot be a subjective term in intersubjective language which could not be explicated behaviorally." Postempiricist philosophers of science have convincingly argued against both of these positions, and neither of them is presupposed or entailed by mental-physical identity theory. Philosophy of science, like science itself, develops in a historical process: as the theoretical context within a field evolves, the theoretical positions that were once taken for granted come to be questioned and on occasion are found to be flawed. The fourth paragraph contains a few minor inaccuracies. It begins with the statement that my position "leads to compartmentalization of psychological and psychiatric concepts," while my position actually describes a functional compartmentalization that is already in effect. The next sentence of the paragraph observes that I criticize "Engel for talking about experience and behavior at the same time." My criticism of Engel is not for talking about experience and behavior at the same time but for implying that they are in the same logical category and that experience is emergent relative to physiological processes. The paragraph concludes with the statement, "Then 'experience' is a behavioral concept which can be coordinated with a subjective concept." I would be willing to consider hypotheses that, within the realm of reality to which the term "experience" applies, there are behavioral concepts which correspond with subjective concepts (such hypotheses would be examples of the "hypotheses of correspondence" or "empirical identifications" to which I refer on p. 557 of my article). I would, however, apply the term "experience" to the subjective aspect of this correspondence relationship, not the behavioral. Learning and behavior theorists generally exclude "experience" from the scientific vocabulary, since it is not directly observable and has no operational definition.

Dr. Setterberg's letter presents a clear and concise review of major points in my article. I particularly appreciate his correction of my unnecessarily limited perspective regarding mental properties at subpersonal and suprapersonal levels of organization. I agree with the statement in Dr. Setterberg's closing paragraph that organic unity theory is a synthesis of the biopsychosocial model and mental-physical identity theory, not a correction of a flaw in the former by use of the latter. However, I continue to believe, for the reasons discussed in my article, that the biopsychosocial model's provision for the mind-body problem—its conceptualization of mind as emergent from brain—is flawed. My final comment on this letter concerns the claim that the biopsychosocial model is not a philosophical theory but a "general conceptual framework for empirical activity." I am not sure how distinct the boundary is between the class of philosophical theories and the class of general conceptual frameworks for empirical activity, and my sense is that the latter is a subset of the former.

Again, I thank the authors of these letters for sharing their thoughts and providing me the opportunity for further development of my own ideas.

### When a Patient Commits Suicide

SIR: The advice of Neil S. Kaye, M.D., and Stephen M. Soreff, M.D. (1) to "contact the family as soon as possible" and "tell them of all the efforts to treat the patient before the suicide" (p.740) did not adequately warn of potential legal or clinical complications. Confidentiality continues beyond death (2, pp. 163–165). A psychiatrist is liable for harm caused by disclosures about deceased patients. This crucial caveat was omitted from the article by Dr. Kaye and Dr. Soreff.

The proposed family interventions omitted discussion of disturbed families whose members are causes or indirect targets of the suicide. For example, in my own practice or supervision the following have occurred.

1. A patient's family was characterized by pathological boundary disturbances. The relative who found the body demanded secrecy about the cause of death, claiming that the knowledge would lead others to commit suicide and would "destroy" family relationships.

2. A patient had a secret history of sexual abuse by a family member and while alive had expressed to her therapist strong wishes that the family never know about her need for treatment. Another clinician's postsuicide family intervention triggered demands by a suspicious member to reveal what had been alleged in treatment.

3. A patient committed suicide in a symbolic manner after an ordinary social act by a family member was experienced as an abandonment. If the clinician had revealed the nature of the suicide, it seemed likely that the family would have ostracized the member whose ordinary act had "precipitated" the suicide.

Drs. Kaye and Soreff implied that other recommendations can be implemented separately from risk management. Thus, advice to communicate with the hospital staff and other patients to minimize adverse effects omitted evaluation of possible legal contingencies. In speaking to staff and patients, one may transform them into potential witnesses. Thus Simon (2, p. 457) advises consultation with an attorney and/or malpractice carrier before making any oral or written statements about an adverse clinical event.

Dr. Kaye and Dr. Soreff presented the malpractice carrier as an optional rather than an essential player in risk management. Giving no reasons, they stated, "Notifying the malpractice insurance carrier *may be* [emphasis added] part of managing the risk. However, we feel this should not be done without first obtaining legal counsel; often it will depend on the practice setting" (p. 742). This prior legal consultation seems unnecessary. It is unlikely that any attorney would advise a client not to notify the malpractice carrier. Furthermore, some policies may include clauses requiring timely notification about risks. While there are advantages to obtaining additional independent legal counsel, this cannot substitute for communicating with the carrier's attorney.

THOMAS E. SCHACHT, PSY.D.
*Johnson City, Tenn.*

SIR: In their otherwise excellent article, written with a great deal of sensitivity, there is conflict between Dr. Kaye's and Dr. Soreff's recommendations concerning doing "grief work" with the family and physicians' ethical considerations. Psychiatrists engage in family therapy on behalf of living patients. When a patient commits suicide, while it is humane and appropriate to meet with the family and to attend the funeral, I do not believe that the psychiatrist should engage in therapeutic exploration of the family's feelings relating to the suicide. Engaging in this kind of therapy fosters the development of new transference relationships. If a family, regardless of whether there is justification, should wish to sue because of the patient's suicide, the fostering of transference between the psychiatrist and the family, even through a single session of grief work, is likely to induce restraint upon the family's decision making. It is not the psychiatrist's responsibility consciously or unconsciously to interfere with the family's decision about whether to litigate.

We have lawyers and physicians providing seminars on prevention of malpractice litigation who deliberately do this very thing: instruct their audience how to influence families emotionally not to sue. As the authors pointed out, a psychiatrist who has rendered quality care should have nothing to fear in instances of frivolous litigation. Unless psychiatric treatment is requested by the family, family therapy following suicide can be construed as unethical behavior.

THEODORE PEARLMAN, M.D.
*Houston, Tex.*

## Dr. Kaye and Dr. Soreff Reply

Sir: Since the publication of our article, we have been deluged with letters, including requests from 10 foreign countries and numerous residency training programs for permission to use the article as part of their residency training curriculums. We are indeed honored.

Regarding the comments of Dr. Schacht and Dr. Pearlman, we would note that each has raised some valid concerns. We agree that to reveal the secrets of therapy would be improper. Furthermore, we are not advocating that clinicians violate the terms of their malpractice insurance. However, we are quite conscious that malpractice carriers have their bottom line, not the psychiatrist's best interests, at heart. The recent case involving two psychiatrists both of whom were insured by the same carrier should convince psychiatrists of this (1).

Both of our colleagues seem to have missed the critical point of the article. First, implicit in their arguments is the notion that if a patient commits suicide, something went wrong which is the fault of the psychiatrist. In reality, suicide does happen. It is a fact of diseases and of practice. Second, doctors are human. The response to a patient's death, especially a suicide, requires a human response. Talking with staff, family, and other patients is advised because it is the natural thing to do and not because we are trying to influence potential witnesses. We must be brave enough to move away from the defensive malpractice paranoia and recognize that along with the family, we too share in the loss.

Furthermore, much has been written about dealing with suicide and suicidal patients. Until now, almost all of it has centered on everyone except the psychiatrist. Now is the time to recognize and to accept that when a patient commits suicide, we need to make time for ourselves as well as for everyone else involved.

## Familial Trichotillomania

Sir: In a letter to the Editor (1), Jacob Kerbeshian, M.D., and Larry Burd, M.S., citing the statement in *DSM-III-R* that familial cases of trichotillomania have not been reported, noted the interesting case of a patient with trichotillomania who had two siblings who also engaged in hair pulling. While little recognized, there have been a number of previous references to familial trichotillomania. For example, Sanderson and Hall-Smith (2) noted a 50-year-old mother with trichotillomania whose 31-year-old daughter also engaged in hair pulling. Similarly, Galski (3) noted two sisters, aged 25 and 27 years, who had pulled out and eaten hair since childhood; since both had begun to pull out hair at about the same time, the author suggested that one might have modeled her behavior after that of the other. Swedo and Rapoport (4) noted that 5% of first-degree relatives of trichotillomanic probands had trichotillomania.

Of 161 adults, adolescents, and children with trichotillomania seen at our clinic, 13 (8%) had first-degree relatives who had pulled out hair (unpublished data). We have now seen two cases of trichotillomania in identical twins; however, neither twin pair was concordant for the behavior. Such observations suggest a possible hereditary predisposition, although Galski's comments regarding modeling should also be given serious consideration.

In 1922 Davis (5) reflected on his 1914 experience with "pseudo-alopecia areata" in an orphanage containing 300 girls under the age of 14; 174 cases of hair loss, characterized by small patches of hair broken off close to the surface, were noted, including three cases in adult staff members. Scalp examinations failed to reveal any clear etiology, and the condition eventually cleared. One year later, another epidemic of 42 cases was noted. Having subsequently seen several cases of hair loss in children secondary to head rubbing and scratching, Davis rejected his earlier theory that the epidemic of alopecia was infectious in nature, noting that cases had developed too rapidly to be explained in this way. Instead, he was of the opinion that these were examples of "mass suggestion" and that the hair loss had resulted from unintentional scratching and rubbing, behavior that was reinforced by attention from attendants and other residents of the orphanage. In a 1933 discussion of trichotillomania (6), Davis referred to the hair loss as the result of hair pulling. Hair pulling in close relatives of trichotillomanic persons, therefore, may not only reflect genetic tendencies toward the disorder but also the impact of environmental modeling. Several hair pullers in our clinic initiated hair pulling after observing another person with the behavior, and families of children with trichotillomania have reported siblings threatening to pull out their hair in order to get their way. The initial concern at presentation for several mothers with trichotillomania was that their children might imitate their behavior.

## Further Comments on Trichotillomania

SIR: In their article, Gary A. Christenson, M.D., and associates (1) discussed the hypotheses that trichotillomania (hair pulling) is a variant of either depression or obsessive-compulsive disorder, but they did not explore its relation to eating disorders, despite noting a high frequency of this comorbidity. In addition. they did not record whether their subjects gave histories of sexual abuse or disclosed significant unresolved sexual conflicts, despite these having been postulated by other authors (2, 3) as possible etiological factors in trichotillomania.

As well as confirming the finding of others that the large majority of hair pullers are female (3), the authors also found that 20% admitted to a history of bulimia nervosa or an atypical eating disorder. Greenberg and Sarner, in their 1965 study (3), found that 12 of the 16 women in a series of 19 patients with trichotillomania "showed a striking overconcern with their weight which went far beyond the usual American woman's concern with slimness, and which amounted to a true somatic preoccupation," despite their normal weight. Since then, other authors (4–6) have reported bulimia nervosa and trichotillomania as coexisting pathologies, including one report of three cases from a series of five bulimic patients which implied that trichotillomania (and trichophagy) might be a common but usually concealed complication of bulimia (6). There is also some evidence that the antibulimic antidepressant fluoxetine can be effective in treating trichotillomania as well (6).

Given that persons with bulimia can be reluctant to disclose their disordered eating, and that this diagnosis is associated with a high prevalence of wide-ranging secondary affective pathology, many of those presenting with trichotillomania could have a hidden concurrent eating disorder. A common etiological factor might be unresolved sexual conflicts that are suppressed through a repetitive (but not necessarily obsessional) pattern of disordered eating, hair pulling, or both and which might lead either directly, or through the effects of the abnormal behavior, to further psychiatric morbidity.

MARK L. TATTERSALL, M.B., B.S., M.R.C.PSYCH.
*London, England*

SIR: The report by Dr. Christenson and associates on hair pulling is problematic because of the extent to which the authors "pathologized" the habit. They asserted that hair pulling is associated with other psychiatric conditions and did not temper their assertion with exceptions. In fact, the authors used the term "psychiatrically disabled" at least twice to describe hair pullers. However, the pediatric, behavioral, and dermatological literatures on hair pulling describe mostly cases in which hair pulling presents as a benign habit that is easily treated with behavior modification, counseling, or even placebo-type interventions. Dr. Christenson and associates imprudently dismissed these literatures by arguing that hair pulling has not been shown to be similar to other benign habits such as thumb sucking. This argument reflects unfamiliarity with existing literature, important aspects of scientific method, or both. Several studies have shown that hair pulling can covary with thumb sucking (1–4), and the designs used in most of them are among the most conservative in science. The findings show that the two habits are often similar and are sometimes even functionally equivalent.

Quite simply, there appear to be different populations of hair pullers. For example, the behavioral literature routinely describes hair pullers without coexisting psychopathology (3, 4). On the other hand, the psychiatric literature describes mostly cases in which hair pulling is part of a constellation of problems. The disparity in the two literatures may reflect variable referral patterns, different subtypes, or a spectrum of severity.

The point of this letter is that at least some (perhaps many) human beings who engage in hair pulling are otherwise normal. Many papers on hair pulling (not just the one by Dr. Christensen and associates) ignore this well-documented point and argue that psychopathology is a necessary co-condition of hair pulling. I assert that such papers do little to help any hair pullers and may actually do harm to those who are otherwise normal.

## Dr. Christenson and Associates Reply

SIR: Dr. Tattersall raises some interesting questions concerning the relation between hair pulling and eating disorders and suggests that these two disorders may share a common etiological factor: unresolved sexual conflicts secondary to a history of sexual abuse. Although we have seen several cases in which a past history of sexual abuse appears to be directly related to the onset of the patient's hair pulling, such an association has been unusual in our experience. Of our initial 60 subjects with trichotillomania, 10 female patients and one male patient (18% total) reported histories of sexual abuse. From Dr. Tattersall's comments, one might hypothesize that these individuals would also have had eating disorders, yet only two subjects had histories of hair pulling, eating disorder, and sexual abuse.

It remains unclear how common the comorbidity of eating disorders and trichotillomania is. In our series of 60 trichotillomanic subjects, 20% had current or past eating disorders, suggesting that the two disorders frequently occur together. It is unlikely that we missed additional cases of eating disorders; we found, as did George et al. (1), that patients appear to find it easier to talk about their eating behavior than their hair pulling.

To clarify further the relation between trichotillomania and bulimia nervosa, we systematically assessed 65 subjects with bulimia nervosa and 40 normal control subjects for the presence of trichotillomania, suspecting that we would find a high number of trichotillomanic persons in the bulimia nervosa group (2). Contrary to our predictions, only one subject with bulimia nervosa and one control subject had trichotillomania, suggesting that the overlap of bulimia nervosa and trichotillomania may not be as common as we and others (1) had suspected. Although Dr. Tattersall cites recent reports of the efficacy of the antibulimic antidepressant fluoxetine in supporting an association between trichotillomania and bulmia nervosa, the open nature of these studies and the possible contribution of motivational factors in these patients must be taken into account. A recent placebo-controlled, crossover study of fluoxetine in trichotillomania completed by our group did not support the efficacy of fluoxetine for this disorder (3).

The observations we have reported here do not support sexual abuse as a necessary or common etiological factor in the development of trichotillomania. A high comorbidity between trichotillomania and eating disorders has been only weakly supported by our data, but further data will need to be collected to answer this question definitively.

In response to Dr. Friman, it is not clear how we "pathologized" the habit of chronic hair pulling. We simply described psychiatric comorbidity that had been systematically assessed in a sample of chronic hair pullers who were primarily self-referred. Dr. Friman appears to ignore our finding that some of our subjects had no additional psychiatric pathology and our acknowledgment that our findings of high rates of psychiatric comorbidity may have been an artifact of sampling. We clearly stated that those whose problems are limited to hair pulling may be less likely to seek help.

Dr. Friman states that we argued that "hair pulling has not been shown to be similar to other benign habits such as thumb sucking"; on the contrary, we suggested that hair pulling might serve a function similar to that of nail biting. We never meant to infer that hair pulling automatically implies that psychiatric comorbidity is present; however, we would caution that failure to look for it may be a great disservice to the patient.

We would agree that the disparity between the psychiatric literature and the other literature on hair pulling may reflect variable referral patterns, subtypes, or a spectrum of severity. We clearly identified our sample as adult chronic hair pullers; our subjects may differ greatly from younger patients or those whose hair pulling may be more brief in duration, although our initial experience with children and adolescents who pull out hair suggests that psychiatric comorbidity is not uncommon (4). Differences in the two literatures might additionally reflect theoretical biases of the researchers and methodological incongruences as well. Dr. Friman claims that the "behavioral literature routinely describes hair pullers without coexisting psychopathology" but fails to acknowledge the lack of systematic assessment for other psychopathology in, and the limited extent of, this literature. In their 1984 review of the behavioral literature, Dr. Friman and associates identified only 25 reports on hair pulling (mostly case reports) covering a total of 64 cases (in eight of which the subjects were mildly to profoundly retarded); they referred to the methodology of the largest study, which included 34 of the 64 cases, as "quasi-experimental." The behavioral, pediatric, and dermatological literature has yet to include reports of systematic evaluations for psychiatric comorbidity in large subject populations.

Not all behaviorists view hair pulling as a simple habit. Mansueto (5), who recently evaluated over 40 people with trichotillomania, stated that his data "challenge the widespread impression that trichotillomania is a simple nervous habit. Instead the problem is revealed as a complex disorder with great variation in individual expression."

We feel that discussing the full spectrum of hair pulling, including psychiatric comorbidity, does more service to hair pullers than to isolate hair pulling as the only problem during assessment or treatment of the disorder or to assume its benign or limited nature on the basis of location of presentation or researcher/therapist bias.

# APA Council Reports

*At the fall component meetings of the American Psychiatric Association in Washington, D.C., on Sept. 11–15, 1991, the APA councils heard reports from their components. Following are summaries of the activities of the councils and their components.*

## The Council on Addiction Psychiatry

Roger E. Meyer, M.D., Chairperson

The Council on Addiction Psychiatry and its subcomponents have a strong commitment to providing psychiatric leadership in the growing field of research, prevention, and treatment of addictive disorders. The council will continue to provide recommendations to APA on training and treatment issues. Currently, two components report to the council.

The *Committee on Training and Education in Addiction Psychiatry,* Robert Niven, M.D., chairperson, continues to discuss the current status of training, both clinical and research, in addictive disorders. At its meetings this year, the committee discussed various training issues, including added qualifications in addiction psychiatry, the Consortium for Medical Fellowships, and a continuing education training project for psychiatrists in the prevention and early identification of alcohol and other drug abuse problems.

The *Task Force on Psychiatric Services for Addicted Patients,* Steven Mirin, M.D., chairperson, was recently established 1) to evaluate the different types of available treatment and advise the council on important issues affecting the role of psychiatry in the treatment of addictive disorders, 2) to monitor, evaluate, and give advice on issues involving current and new funding mechanisms and problems, including coverage under various funding schemes, and 3) to alert the council and the field, when appropriate, if problems or important issues become obvious. At its first meeting, on Sept. 11, 1991, the task force spent a great deal of time discussing the role of psychiatrists in substance abuse treatment and appropriate funding mechanisms for this treatment. The importance of liaison with other APA components and outside organizations was emphasized during this discussion. The task force also reviewed the "Criteria for Levels of Care for Reimbursement," the "American Society of Addiction Medicine's Patient Placement Criteria for the Treatment of Psychoactive Substance Use Disorders," and the Medicaid Substance Abuse Treatment Act of 1991.

The council itself considered a number of important items during the year. A great deal of time and effort has been spent on the proposal for added qualifications in addiction psychiatry. Late last year APA's Assembly of District Branches voted to approve this proposal. Recently the American Board of Psychiatry and Neurology (ABPN) and the American Board of Medical Specialties approved APA's recommendation for these added qualifications. APA, through the council, will continue to work with the ABPN on the development of a certification examination, to be presented in the next few years.

At its meetings throughout the year, the council spent a great deal of time discussing the possible reorganization of the Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA). The council is concerned not only about the future of research at the National Institute on Alcohol Abuse and Alcoholism and the National Institute on Drug Abuse but also about the role of psychiatrists in the services system and the need for careful evaluation of prevention and treatment demonstration projects. At its meeting on Sept. 12, 1991, the council expressed its concern about the lack of an official APA stand concerning this reorganization. The council agreed to communicate to the APA Work Group on Federal Government Organizational Structure, the Joint Commission on Government Relations, and the Board of Trustees a set of principles to be included in APA's recommendations concerning this reorganization.

The council discussed the possible development of practice guidelines for substance abuse treatment. The council has expressed its desire to work with the Steering Committee on Practice Guidelines in developing such guidelines.

Because it agrees that nicotine dependence is a major public health problem, the council discussed the possible development of a task force on nicotine dependence. This task force, which would report to both the Council on Addiction Psychiatry and the Council on Research, would educate psychiatrists regarding the seriousness of nicotine addiction and the need for treatment; assess current scientific information in the field related to clinically relevant basic science data, treatment approaches, and implications of comorbidity with other psychiatric conditions; recommend reimbursement issues that need to be explored; develop recommendations for training and curriculum development for psychiatric residency programs; and establish a general research agenda. This recommendation was approved by the Joint Reference Committee in October 1991 and is scheduled to be presented to the Board of Trustees for its final approval in December. The council continues its involvement in the ADAMHA Primary Care/Substance Abuse Linkage Initiative, which was established to strengthen the links between and integration of the primary health care system and the alcohol abuse, drug abuse, mental illness, and HIV/AIDS treatment systems. Recently the council forwarded names of individuals for consideration as speakers at the upcoming Secretarial Conference on Primary Care and Substance Abuse Linkage.

The council recommended that APA support the Women and Alcohol Research Equity Act as a bill that would require additional funding. This recommendation was approved by the Board of Trustees and was communicated to Congress by the Division of Government Relations.

The council recommended that APA support the Medicaid Substance Abuse Treatment Act of 1991, recognizing that treatment services should also be covered in appropriate settings other than residential ones, under medical supervision. The council also recommended that APA become an organizational member of the National Coalition on Alcohol and Other Drug Issues. These recommendations were approved by the Joint Reference Committee in October 1991 and are scheduled to be presented to the Board of Trustees in December for its final approval.

The council looks forward to addressing several important issues related to addiction psychiatry in the coming year. These issues include continued development of a certification examination for added qualifications in addiction psychiatry, programs for clean needle and syringe exchange, and the inclusion of detoxification in the American Medical Association's basic insurance benefits package.

# The Council on Aging

Jerome A. Yesavage, M.D., Chairperson

The Council on Aging has had an extremely productive year. Two components completed their reports, and publication by APA is now pending. A third report is expected to be completed and approved for publication in early 1992. The Board of Trustees has approved the establishment of the council's second committee, the Committee on the Ethnic Minority Elderly. The council also received approval to establish the Work Group on Model Standards for Private Long-Term Care Insurance. Finally, the Task Force on the White House Conference on Aging has convened an interdisciplinary coordinating group to assist in the preparation of a mini-conference on mental health in anticipation of the 1993 White House Conference on Aging.

Council members continue their extensive collaboration with other APA components and offices and with other medical organizations. For example, the Council on Aging will participate with the Council on Psychiatry and Law in the work of the intercouncil Subcommittee on the Impaired Driver. The Council on Aging will work closely with the Council on Medical Education and Career Development to monitor issues related to education and training in geriatric psychiatry. The Council on Aging continues to maintain close working relationships with APA's Division of Government Relations and with the National Institute of Mental Health (NIMH).

In 1990 the council initiated a formal working relationship with the American Association for Retired Persons (AARP) and recommended to the Joint Reference Committee and the Board of Trustees that APA also participate in AARP activities. In 1991 council members represented APA at meetings of the AARP mental health forum; other council members worked with an AARP leadership group on health care policy. The council is also closely cooperating in the design and dissemination of an AARP-sponsored survey on nursing home care issues, and individual council members provided guidance to AARP staff in development of AARP publications of interest to the elderly population.

Council members routinely provide expertise and advice on complex federal laws and regulation governing the care of the elderly. In response to the request and guidance of one member of the council, Senator John Chafee (R-R.I.) recently introduced federal legislation to repeal the discriminatory Medicare 50% copayment required of nursing home residents who receive mental health care.

In response to a coordinated effort by the Council on Aging and the APA Division of Government Relations, committees in the U.S. Senate and the U.S. House of Representatives have approved legislation to facilitate federal assistance to programs for education and training in geriatric psychiatry.

Members of the Council on Aging were particularly active in conveying to their federal elected officials their concerns about the impact on geriatric psychiatry of the new resource-based relative value scale (RBRVS) Medicare fee schedule; the final rule on the RBRVS as published in late November substantially improved Medicare payment to psychiatry under the new fee schedule. The members of the Committee on Long-Term Care and Treatment for the Elderly have been particularly effective in assisting the APA Division of Government Relations in commenting on, and obtaining changes in, proposed federal regulations governing the general care and treatment of nursing home residents, in particular, regulations governing the use of psychotropic medications for the nursing home population.

Virtually all council components met during the 1991 annual meeting in New Orleans, and they also met during the 1991 fall component meetings in Washington, D.C. The council will also convene for its January 1992 meeting in Washington, where members will meet with key Congressional staff and with members of Congress. The January meeting provides a unique opportunity for the members of the council to develop personal and professional relationships with Congressional staff and members of Congress who are directly involved in the development of federal policy affecting geriatric psychiatry and in other federal issues of concern to the council.

The *Task Force on the White House Conference on Aging,* Sanford Finkel, M.D., chairperson, reported that, after numerous false starts, the President finally announced the convening of a decennial White House Conference on Aging in 1993. In preparation for the White House conference, the task force is working with representatives of the psychology, social work, and nursing professions to develop an agenda for a mental health mini-conference to be held before the 1993 White House Conference on Aging. With support from NIMH, representatives of the four disciplines met in Washington in October 1991 to review the record of the last White House Conference on Aging (in 1981) and to prepare a paper for NIMH on the progress toward meeting the mental health goals adopted by that conference. This paper, which is preparatory to the mini-conference, is already well underway; a second meeting of the coordinating group will be held in January 1992 to complete work on the paper.

The *Committee on Long-Term Care and Treatment for the Elderly,* Ira Katz, M.D., chairperson, and the *Task Force on Reimbursement Options and Alternatives in the Psychiatric Care of Older Persons,* Howard Goldman, M.D., chairperson, continue to meet concurrently. At the direction of the Council on Aging, the committee jointly sponsored with NIMH a 1-day panel on the use of psychotropic medications for the elderly nursing home population. The panel led the committee to propose a position statement on the use of psychotherapeutic medications for nursing home residents. (The position statement was approved by the Assembly of District Branches in November 1991.) The panel will also lead to the development of a supplement to the committee's 1989 report on the mentally ill elderly in nursing homes (1).

Members of the committee and the task force continued to provide expert assistance to APA's Division of Government Relations on issues related to nursing home care and federal reimbursement for psychiatric services under the Medicare program. To that end, Dr. Goldman was a featured speaker at a Division of Government Relations presentation to key Congressional health care staff on the proposed RBRVS rule and its adverse impact on psychiatry.

In response to a Board directive, the committee and the task force recommended that APA establish a work group on model standards for private long-term care insurance to develop and recommend policy standards aimed at eliminating discrimination in long-term care insurance against individuals requiring treatment for mental illness. Current insurance standards governing the issue are extremely weak. Although the Work Group on Model Standards for Private Long-Term Care Insurance was approved, funding is still pending. The work group hopes to begin its work in 1992.

The *Task Force on Models of Practice in Geriatric Psychiatry,* Marion Goldstein, M.D., chairperson, has completed its draft report. Council consideration of the draft report is expected in early 1992. In addition, the task force conducted a workshop on comparative models of practice at the APA 1991 annual meeting.

The *Task Force on the Ethnic Minority Elderly,* Kenneth M. Sakauye, M.D., chairperson, completed its report, which was subsequently approved for publication by the Joint Reference Committee and the Board of Trustees. One of the recommendations was that the task force be converted to a permanent committee. That recommendation was approved, and the task force became the Committee on the Ethnic Minority Elderly. The committee will meet beginning in 1992, and it will work closely with APA components, such as the Council on National Affairs, on issues of mutual concern.

The *Corresponding Task Force on Geriatric Psychiatry in the Public Mental Health Sector,* Barry Fogel, M.D., chairperson, completed its report, "Geriatric Psychiatry in the State Mental Health System." The report was subsequently approved for publication by the Joint Reference Committee and the Board of Trustees. Publication is expected in the near future.

The *Task Force on Education and Training in Geriatric Psychiatry,* Charles Shamoian, M.D., chairperson, has seen the fruition of its major federal legislative initiative: the expansion of federal support to programs of education and training for geriatric psychiatry. To that end, committees in the U.S. House of Representatives and Senate have approved legislation to amend Title VII of the Public Health Service Act to expand opportunities for fellowship funding for training in geriatric psychiatry and to permit departments of psychiatry to be a locus of geriatric training. Final federal legislative action is expected in early 1992.

In conclusion, the Council on Aging and its components expect 1992 to be another busy and productive year, marking anew the impact the council continues to have on key health care policy issues affecting the care and treatment of geriatric patients.

---

# The Council on Children, Adolescents, and Their Families

Mohammad Shafii, M.D., Chairperson

The council continued to address its charge—to maximize APA's effectiveness in addressing the mental health needs of children, adolescents, and their families—in every aspect of its work.

At the close of the May 1991 meeting, Dr. Shafii assumed leadership of the council from Dr. Lawrence Stone, who was appointed to serve as a consultant. Dr. Donald Gair was appointed as a new member of the council. Drs. Clarice Kestenbaum and James MacIntyre, who had been appointed as corresponding members, were available to participate in person at the May meeting. Dr. Richard Athey, APA/Burroughs Wellcome Fellow, and Dr. Alice Mao, APA/NIMH Fellow, rotated off the council. In September 1991 the fellowship positions were filled by Drs. Michael Kaplan and Cydney Parker.

The *Committee on Chronically Ill and Emotionally Handicapped Children,* Cynthia Pfeffer, M.D., chairperson, established an active liaison with the Committee on the Chronically Mentally Ill, which is housed within the Council on Psychiatric Services. In addition, the committee has met with representatives of lay groups. Both of these efforts have helped the committee in its deliberations about community services for chronically mentally ill children and adolescents. To provide a smooth transition, Dr. Pfeffer assumed the role of consultant when Dr. Kendon Smith was appointed chairperson of the component. The council accepted Dr. Smith's recommendation that APA request the National Institute of Mental Health (NIMH) and private foundations to solicit proposals for epidemiological studies of chronic mental disorders in children and adolescents.

The *Committee on Family Violence and Sexual Abuse,* Sandra Kaplan, M.D., chairperson, developed a position statement on child abuse (1), which was approved by the council and subsequently by the Joint Reference Committee and the Board of Trustees. A major effort of the committee has been the development of "Family Violence: A Clinical Guide." It is anticipated that the book will be completed in the near future.

The *Committee on Psychiatry and Mental Health in the Schools,* Irving Berkovitz, M.D., chairperson, completed the "Position Statement on School-Based Health Clinics" (2), which was approved by the council, Joint Reference Committee, and Board of Trustees. The committee is close to completing a monograph, "Psychiatric Involvement in the Schools." The committee intends to develop a shorter version of the document for distribution to school districts and to assess the interest of district branch presidents and editors of district branch newsletters in forming networks of psychiatrists who consult in schools.

The *Work Group to Develop a Handbook for Psychiatric Practice Related to the Juvenile Justice System,* Michael Kalogerakis, M.D., chairperson, completed the *Handbook of Psychiatric Practice in the Juvenile Court.* The book is being published by the American Psychiatric Press and will be available by the end of 1991. Expressing thanks for an excellent job, the council voted to disband the component and to express appreciation to the Kenworthy-Swift Foundation for funding the project.

Even though deeply saddened by the sudden and unexpected death of member Dr. Edward Futterman, the *Committee on Juvenile Justice Issues* continued to operate smoothly as the leadership shifted from Dr. William Buzogany to Dr. Richard Marohn. The committee completed a report, "The Psychiatrist and the Juvenile Justice System" (3), and is in the process of reworking the "Position Statement on the Capital Punishment of Minors." After a review of the available data related to the charge of inappropriate hospitalization of adolescents, the committee recommended the establishment of a task force on the use and abuse of hospitalization of children.

The *Task Force to Study the Use and Abuse of Hospitalization,* Elizabeth Weller, M.D., chairperson, held its first meeting in September 1991. The component plans to be a clearinghouse for the accumulation and storage of information and guidelines developed by other organizations, to review data bases, to develop a position paper on practice guidelines for physicians, and to develop facts for families.

Pursuant to the recommendation of the Board of Trustees, which provided money for the first meeting of the component, staff is seeking outside funding for the continuation and completion of the assignment of the task force.

The *Task Force on the Psychiatric Aspects of New Reproductive Technologies,* Miriam Rosenthal, M.D., chairperson, expects to complete its monograph by winter 1992. All recommendations will pertain to psychiatry, although the task force is multidisciplinary.

The *Task Force on Day Care for Pre-School Children,* Myron Belfer, M.D., chairperson, developed a position statement on day care. The group emphasized the importance of day care, that sometimes it is not a matter of choice for parents but a necessity. The APA membership is being asked to maintain constant vigilance about day care, as is the Joint Commission on Government Relations. Groups of residents and fellows within APA are also being asked to lobby for ongoing attention to day care.

Each component developed a workshop or symposium for the 1991 annual meeting. The council joined Board of Trustees member Herbert Sacks, M.D., in planning and participating in an annual meeting workshop on custody and visitation.

The council has developed active liaisons with the Council on International Affairs (regarding the plight of Rumanian children and children in the Near East), the Council on Research (regarding ongoing NIMH funding for research on children and adolescents), the Task Force on the Homeless Mentally Ill (under the Council on Psychiatric Services), the Committee on Human Rights (under the Council on International Affairs), and the Committee on the Chronically Mentally Ill (under the Council on Psychiatric Services).

The council received a report on the development of the Board of Adolescent Psychiatry and plans to develop a formal response. After a review of materials that address the development of a subspecialty in neurodevelopmental pediatrics, the council recommended that APA communicate to the American Academy of Pediatrics and the American Board of Pediatrics APA's concern about the lack of coordination in the development of curricula for specialists who serve children and youth. The council has also recommended development of dialogue regarding coordinated planning to best meet the needs of children and youth.

# The Council on Economic Affairs

Robert Gibson, M.D., Chairperson

The activities of this council and its components during 1991 reflect APA's continued efforts to influence the many commercial and governmental entities that affect the provision of psychiatric care. Members of the council and its components maintained liaison with representatives of such organizations as the Social Security Administration, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), the Health Care Financing Administration (HCFA), and major managed care and insurance companies.

The *Committee on Financing and Marketing,* Robert O. Friedel, M.D., chairperson, has focused on marketing assistance for APA members, primarily through the district branches. Its major concerns include negative trends in corporate response, decreasing insurance benefits for psychiatric care, inappropriate utilization management activities, and a blurring of the roles of psychiatrists and psychologists. The committee has set the following goals for the year: 1) updating the APA marketing manual for district branches, 2) reviewing and editing a new chapter on marketing psychotherapy for inclusion in the manual, and 3) submitting a workshop proposal for the 1992 annual meeting.

The *Committee on Hospital-Based or Hospital-Related Services,* Boris Astrachan, M.D., chairperson, involved itself with an analysis of the efforts of the JCAHO to improve communication with participating organizations and restructure the professional and technical advisory committees. The committee alerted the council that the restructuring could significantly weaken the professional and technical advisory committees and diminish the role of participating organizations. The committee will continue to take a proactive stance and urge the JCAHO to strengthen the professional and technical advisory committees and improve their functioning. The committee also reviewed and commented on research conducted through a National Institute of Mental Health (NIMH) grant relating to a model mental health benefit.

The *Committee on Interprofessional Affairs,* William Webb, Jr., M.D., chairperson, continues its work with the Joint Commission on Interprofessional Affairs. The commission is made up of representatives from APA, the American Psychological Association, the National Association of Social Workers, and the American Nurses' Association. In 1991 the joint commission engaged in efforts to define each of the professions represented by the four organizations. It is anticipated that the document, "Content of the Professions," will be published in 1992. Additionally, the Joint Commission on Interprofessional Affairs continued its planning for a 1993 conference on interdisciplinary collaboration and explored many issues of mutual interest, including managed care, national health insurance, prescribing privileges for psychologists, and continuing education.

The *Committee on Managed Care,* Steven Sharfstein, M.D., chairperson, continues to address issues for psychiatry and managed care through support of legislation and regulation, research, education, and dialogue with the managed care industry. Special projects this year included publication and distribution to the membership of "Utilization Management: A Handbook for Psychiatrists," sponsorship with the Ethics Committee of the Conference on Ethics in Managed Care for Psychiatry (publication and distribution of the conference proceedings is anticipated), an annual meeting workshop on ethics in managed care, activation of the network of district branch managed care liaisons and initiation of local efforts in managed care, and initiation of a series of meetings with managed care organizations to discuss problems documented through APA's 800-number telephone service and to seek redress at the policy level. The committee continues to support managed care regulation activities, the continuing review and presentation of cases documented through the 800-number (1-800-343-4671) telephone service, and support of medical necessity criteria review in conjunction with other APA components.

The *Committee on Occupational Psychiatry,* Peter L. Brill, M.D., chairperson, has had a very full agenda during 1991, has submitted proposals for two workshops and a component workshop for the 1992 annual meeting, and is preparing a course for the 1993 annual meeting. During the year three text books, one of which will be published by American Psychiatric Press, Inc. (APPI), were written by psychiatrists who are members of the committee. The committee further reported that the Academy of Occupational and Organizational Psychiatry will meet in January 1992 and at the APA annual meeting in May. The agenda of the January meeting includes managed care, cultural change, and organizational consulting.

The *Committee on Quality Assurance,* George F. Wilson, M.D., chairperson, has completed its revision of the *Manual of Psychiatric Quality Assurance* with the assistance of other components and with peer review by multiple members of the association. The revised manual is now scheduled for publication by APPI in December of 1991. It is hoped that it will be useful for reviewing the history of the Association's involvement in utilization review activities and that the publication of the criteria used by the utilization reviewers will be helpful to members currently engaged in managed care. The Committee on Quality Assurance has been reconstituted as a smaller committee. During the last year it has begun its review and critique of the various criteria, standards, and screens affecting psychiatrists that are published by other organizations and the federal government. A great deal of time has been required for the review of the HCFA generic quality screens for hospital inpatient care, which have come under some criticism by members because of the use of the screens in general hospital psychiatric units, where they do not seem to be appropriately applied. It is hoped that the very precise and in-depth review and commentary given by the committee will be useful as the Association seeks to carry on its negotiations with the HCFA to work out meaningful revisions in the generic quality screens for hospital inpatient care. This is an example of the work the Committee on Quality Assurance will continue to do as it carries out its new charge.

In its initial meetings, the newly formed *Committee on Universal Access to Health Care,* Herbert S. Sacks, M.D., chairperson, refined its mission and planned its agenda. The committee's tasks are 1) to disseminate information to the broad membership relating to universal access to health care, through articles in APA publications and through programs at the annual meeting and regional meetings, 2) to develop a knowledge base and keep abreast of developments in health care economics as they pertain to universal access to care, 3) to study global issues involving health care delivery systems, 4) to serve as a resource to the Board of Trustees as it develops APA policy on universal access, and 5) to interact with other APA components both to receive relevant input and to provide consultation as indicated. The committee's specific activities will include preparation of a bibliography identifying approximately six publications on universal access and submission of a number of articles to *Psychiatric News* on topics such as developments in the states, international developments, and Congressional actions.

The *Task Force on Prospective Payment Issues,* Joseph T. English, M.D., chairperson, continued to monitor payment issues and to explore potential alternative payment mechanisms. Among these efforts was a review of NIMH studies of federal legislative and administrative activities related to prospective payment for psychiatry. The task force believes there are no immediate threats to psychiatry's exempt status, and it continues to work closely with the Prospective Payment Assessment Commission as it works to improve reimbursement under the Tax Equity and Fiscal Responsibility Act of 1982 (TEFRA). The task force is monitoring several innovative payment reform initiatives underway in the states. These are being watched closely by the federal government and the field.

The *Work Group on Codes and Reimbursement,* Chester Schmidt, Jr., M.D., chairperson, conducted an in-depth review of the *Physicians' Current Procedural Terminology, 4th edition* (*CPT-IV*), which will be published by the American Medical Association. The APA membership will be educated about the evaluation and management codes through presentation of a workshop at the November 1991 meeting of the Assembly and an article to be published in *Psychiatric News.* Additionally, proposals for a course on *CPT* basics and a workshop for the 1992 annual meeting have been submitted. The work group reported that it will resurvey the Medicare intermediaries to determine whether there are problems in giving psychiatrists access to the evaluation and management codes.

The *Work Group on the Harvard Resource-Based Relative Value Scale Study,* Donald Scherl, M.D., chairperson, continues to address the proposed RBRVS Medicare fee schedule. Although the RBRVS was expected to result in an increase in payments for "cognitive" services, including psychiatry, the HCFA proposal would in fact be highly damaging to psychiatry, cutting average payments for psychiatric services by 9% in 1992 and by 5% over the full 5-year phase-in. The HCFA proposed the percentage cut primarily because it included a $3 billion "behavioral offset" fund in its budget. The HCFA anticipated this fund would be needed to offset an increased volume and intensity of services by physicians when payments are reduced under the new fee schedule. Through a complex budget procedure, the behavioral offset would be "leveraged" onto undercompensated cognitive services, resulting in a 16% payment cut.

Numerous statistical, methodological, and conceptual flaws in the proposed RBRVS for psychiatry have been identified. They include problems with data collection and analysis, undervaluation of the relative values for psychiatric work, cross-specialty links, geographic factors, and more. Concluding that the RBRVS proposed for psychiatry is so fundamentally flawed that it could not be fixed by the October 1991 publication of the final rule, APA sought a 1-year delay in its application to psychiatry.

APA and the work group testified before the several relevant committees of the U.S. House of Representatives and Senate, submitted initial comments on the proposed rule, communicated APA concerns to all 535 members of Congress, and coordinated a massive APA grassroots letter-writing campaign. Additionally, APA concerns were communicated during meetings with senior HCFA policy staff. During a 1-day meeting, experts in health economics analyzed the proposal and assisted in the preparation of APA's response. Some 45 pages of final comments were submitted, as well as additional HCFA-requested materials relating to specific RBRVS "fixes" to address psychiatry's concerns. Further, APA hosted a briefing on the RBRVS for the members of the Republican Health Task Force in the House of Representatives.

# The Council on Internal Organization

Charles B. Wilkinson, M.D., Chairperson

The council oversees "all those matters involved in the organizational structure of the Association not covered by constitutional committees." Eleven components report directly to the council, and 15 other components report to committees under the council: 11 award boards report to the Committee on Grants and Awards, and three subcommittees and a task force report to the Scientific Program Committee. Components of the council cover many areas of responsibility: 1) annual meetings—including program content, exhibits, arrangements, and awards given during meetings in recognition of outstanding achievement, 2) information systems—including data processing and telecommunications, 3) benefits offered to members and to APA staff, 4) maintenance of the APA headquarters building, 5) advertising policy, and 6) the federation of auxiliary organizations. Following are the highlights of council and component activities over the past year.

The *Committee on Advertisers and Exhibitors,* Maurice J. Martin, M.D., chairperson, recommended in September 1991 that the revised guidelines on pharmaceutical or other industry-sponsored symposia be expanded to include the Institute on Hospital and Community Psychiatry, as well as the annual meeting. The committee continues to monitor exhibitors' activities during meetings to ensure compliance with the established guidelines. These guidelines, approved for the annual meeting by the Board of Trustees in 1983, were expanded this year to include the H&CP institute.

The *Committee on Advertising,* William D. Strathmann, M.D., chairperson, serves as an advisory body to the editors of APA's three periodicals (*Psychiatric News, American Journal of Psychiatry,* and *Hospital & Community Psychiatry*) on questionable advertisements that either have been submitted for publication or are being considered for solicitation for publication. The committee works closely with the Committee on Advertisers and Exhibitors to keep the latter informed about advertisements it recommends for rejection. As of October, the committee had not been asked by the editors to review any advertisements in 1991. The committee reviewed only two advertisements, both for screening tests, in 1990.

The primary goal of the *Committee on Friends of the APA,* Linda Logsdon, M.D., chairperson, is to identify, recruit, and organize spouses and partners of APA members who are not eligible for the APA Auxiliary or the Lifers Group. The one group under the committee at this time is the APA Auxiliary, which includes spouses of APA members.

The *Committee on Grants and Awards,* Mary Jane England, M.D., chairperson, is reorganizing the Association's awards program, as requested by the Board of Trustees in March 1990. The Board was concerned about the adequacy of the oversight provided by councils to the awards components. The goal of the reorganization is administration of each award by a council that deals with the particular area of the award; i.e., an award for child psychiatry would be administered by the Council on Children, Adolescents, and Their Families. Discussions with the councils concerning assignment of specific awards are continuing. While the reorganization is being further developed, the Board requested an interim measure: presentation to the Board in September 1991 of a list of award winners who will give lectures during the 1992 annual meeting. Other committee actions include the following: 1) the recommendation that the "Foundations' Fund Prize" be changed to the "APA Award for Research," 2) finalization of criteria for the Human Rights Award, which is given to individuals or organizations exemplifying the capacity of human beings to protect others from harm inflicted by other human beings, and 3) approval of the William Sorum Awards, a group of Assembly awards for district branches with significant achievements in Member-in-Training involvement.

The *Headquarters Committee,* Lucy D. Ozarin, M.D., chairperson, continues to oversee the routine functions of the headquarters facility and to review specific issues when they arise. The council directed the committee to review its charge with emphasis on carrying out its designated functions.

The *Committee on History and Library,* Martha J. Kirkpatrick, M.D., chairperson, is seeking outside funding for the Rare Books Room within the APA Library and hopes that the room will be completed in time for APA's Sesquicentennial celebration in 1994. The committee is planning activities in conjunction with the Sesquicentennial, including workshops, preparation of a bibliography of rare books, and a photography exhibit.

The *Committee on Human Resources,* Jack W. Bonner III, M.D., chairperson, was formerly the Personnel Committee. This committee recommended a number of additions to the APA personnel manual, including policies on conflicts of interest, ethics, drugs in the workplace, sexual harassment, and smoking. The committee has asked staff to explore ways of reducing benefit costs and the feasibility of offering flexible benefits to staff.

The *Committee on Information Systems,* Zebulon C. Taintor, M.D., chairperson, has found that APA's course in data processing is highly cost-effective and is progressing well and reasonably. The challenge of data processing in a setting such as APA is to orchestrate the acquisition of hardware and software so that the individual components can carry out their myriad, diverse functions while preserving a core of common software and backup support. The committee is also considering how best to work with the Steering Committee on Practice Guidelines on software for the guidelines. As a service to members, the committee held a workshop during the 1991 annual meeting and plans to hold another in 1992.

Allan Tasman, M.D., chairperson of the *Scientific Program Committee,* reported that the 1991 annual meeting in New Orleans had over 13,000 attendees and was among the top three annual meetings ever in terms of attendance. The committee continues to refine the program, adding formats such as the newly established Round Table Discussions and Forums, both of which will become a regular part of the program. Continued funding of sign-language interpreters during APA's annual meetings is being discussed with the Caucus of Hearing-Impaired Psychiatrists and Psychiatrists Working With Hearing-Impaired Patients.

Two changes in the exhibits have been suggested: 1) suspension of solicitation and display of scientific exhibits at annual meetings and H&CP institutes, beginning with the 1992 annual meeting, since these exhibits seem to have been absorbed by the scientific program, and 2) an increase in the fees for industry-sponsored symposia, beginning with 1993 annual meeting.

The *Committee on Special Benefit Programs,* Eva V. Ebin, M.D., chairperson, continues to develop member programs, including the Legal Consultation Plan and Gold MasterCard. The Member Retirement Planning Program, in effect for 8 months, has received a great response: more than 2,000 members have requested and received prospectuses and questionnaires. The "Law and the Practice of Psychiatry" and "Career Choices in Psychiatry" seminars continue to thrive. Other programs being developed include discount office equipment (such as fax machines).

The *Committee on Telemedical Services,* Jonathan D. Lieff, M.D., chairperson, is unique in medicine, since it monitors developments in telemedicine, a field that has great potential both for helping the suffering and for exploitative and hazardous misuse. The council recommended that the committee focus on the committee's original charge: defining the ethical use of telecommunications in medical services, clarifying medical-legal problems, reviewing potential activities with other medical groups, and studying the cost-effectiveness of teleconferences versus in-person meetings. The council is also discussing with the committee its functioning, the value of telecommunications for psychiatry, and the future work of the committee.

Also discussed by the council was a proposal, presented by APA management staff, for saving money on APA travel by contracting with a vendor to provide the lowest applicable nonrefundable air fares. This proposal was subsequently presented to the Board by the Budget Committee and approved.

The council would like to thank Dr. Thelissa Harris for stepping in as acting chairperson during the fall component meetings, when neither the chairperson nor vice-chairperson was available.

# The Council on International Affairs

Eugene Feigelson, M.D., Chairperson

The Council on International Affairs is the membership component that oversees APA's international activities and makes policy recommendations to the APA Board of Trustees related to activities international in scope. It deals with all questions pertaining to psychiatry and international relations that are presented by APA members, other components, psychiatrists from other countries, and staff.

The council and the components that report to the council have initiated a number of important projects this year, and the council has taken on the responsibility of defining APA's role in the "new world order." The council is involved in projects that can potentially affect many countries in the world and projects that are more regional. In addition, the Office of International Affairs has close contacts with psychiatrists in over 80 countries around the world, and these contacts have proven to be valuable resources for APA members, especially in the area of patient referrals and collaborative ventures.

This year one of the projects that has been a focus of the council's work is our bilateral exchange with colleagues in Poland, Czechoslovakia, and Hungary. This exchange will take place from March 25 to April 12, 1992, in Krakow, Poland; Prague and Bratislava, Czechoslovakia; and Budapest, Hungary. Funding is being provided by the Upjohn Company. A team of 12 American psychiatric experts are traveling to these countries to present lectures on areas of mutual interest and to receive information about these special aspects of psychiatry in each country. If funding is secured for this project in future years, the next phase will focus on Romania, Bulgaria, and the Baltic states and in subsequent years it will involve other parts of the world.

The council was pleased with the very successful joint meeting with the Caribbean Psychiatric Association, which was held in Barbados in May 1991. More than 200 APA members attended this meeting, which focused on substance abuse, forensic psychiatry, mental health delivery systems, children, and geriatrics. Special appreciation is extended to Dr. Richard Fields of Atlanta and to Dr. George Mahy of Barbados for their leadership in making this conference such a success. This was the last in a long series of jointly organized scientific conferences sponsored by APA and psychiatric organizations in other countries. The council was compelled to suggest that these meetings be ceased unless additional staff is allocated for the Office of International Affairs, and APA's diminishing financial resources preclude the addition of staff. The Office of International Affairs does maintain an extensive international meetings list, which can be distributed on request.

APA has agreed with a council recommendation that APA cosponsor a Soviet-American conference on ethics in psychiatry with the Georgetown-Johns Hopkins Universities Program in Law, Ethics, and Health; the University of Wisconsin Program in Medical Ethics; and the Yale Law School Schell Center for International Human Rights. Dr. Loren Roth has been appointed as the official APA representative to serve on the organizing committee for this conference, and the process for nomination of Soviet members has begun. This conference will probably take place in late 1992 or early 1993.

The council continues to be pleased with the International Scholars Program at the APA annual meeting and would like to express its appreciation to the Scientific Program Committee for its efforts in increasing the number of international presentations on the annual meeting program. It is hoped that the services and assistance available for international visitors will be enhanced at the 1992 annual meeting. Approximately 2,000 participants from other countries attend each annual meeting, and the council would like to make them feel as welcome as possible.

The *Committee on International Education,* Normund Wong, M.D., chairperson, is disappointed that the International Medical Scholars Program administered by the Educational Commission on Foreign Medical Graduates no longer includes psychiatry because of the lack of funding. APA's Committee on International Education was to provide the psychiatric component of that project. However, the committee and the council are hoping to obtain outside funding for establishment of international guidelines for psychiatric curricula. The first phase of the project would bring together distinguished psychiatric educators from South and Central America for a series of seminars to discuss these issues and make proposals that could be shared with educators in the United States and other countries. If the first phase is successful, funding would be sought to continue these seminars in other parts of the world. Collaboration with the InterAmerican Council of Psychiatric Organizations and the Pan American Health Organization will be sought as the project moves ahead.

In addition, this committee and the council are seeking outside funds for an international directory of psychiatry that would build on the network already established by the Office of International Affairs. Key psychiatric officials around the world would be surveyed with specific questions of interest. Once the information was obtained, the directory would be published and available for distribution. The specific areas to be covered relate to psychiatric training, certification, services, demographic characteristics of mental health professionals, and major mental health concerns in each country.

The *Committee on Human Rights,* Loren Roth, M.D., chairperson, has now completed the booklet "Psychiatry and Human Rights" and has submitted it for consideration by the APA leadership. This booklet discusses reasons for psychiatric involvement in human rights issues and provides information about APA's work in this area. The committee is especially pleased with the new APA Human Rights Award, which will be presented for the first time at the APA 1992 annual meeting. Nominations have been received from the APA membership, and efforts to obtain outside funding for the award are still underway. The committee has also received approval for an official APA form for inquiries into individual cases of alleged human rights abuses. The committee has written a number of letters of inquiry about individual cases and hopes that an official APA inquiry form will increase the likelihood of response.

The committee and APA President Lawrence Hartmann are organizing a Presidential Symposium on "Psychiatry and Human Rights," which will be presented at the 1992 APA annual meeting. Presentations will made by Dr. Chester Pierce, Mr. Eric Stover, Dr. Inge Kemp Genefke, Dr. Samuel Martinez-Lara, and others.

The *Committee on International Abuse and Misuse of Psychiatry and Psychiatrists,* D. Raymond Freebury, M.D., chairperson, has continued to monitor psychiatric abuses around the world and to make recommendations to the APA leadership for possible action. The committee was very interested in the World Psychiatric Association's site visit report on Soviet psychiatry, which was written by a team headed by Dr. J.L.T. Birley of Great Britain. APA members on this team included Dr. Loren Roth, Dr. Vladimir Levit, Dr. Felix Kleyman, and Dr. Ala Levit. However, the report revealed that the All Union Society of Psychiatrists and Narcologists of the Soviet Union has been, at best, only perfunctory in its efforts to meet some of the conditions outlined by both the World Psychiatric Association (WPA) and APA. Thus, the Board of Trustees indicated that in the light of political developments in the Soviet Union, the WPA should be prepared to expand its contacts with Soviet psychiatry by recognizing recently established and newly emerging psychiatric associations as they fulfill the standards and requirements of the WPA. In addition, the Board of Trustees believes that the All Union Society's membership in the WPA should be revoked. The committee continues to seek additional ways to help psychiatric associations that wish to eliminate political abuse of psychiatry in their countries.

The council has asked the committee to begin work on an international "bill of rights" for patients, which might be submitted to the WPA for its adoption. A number of countries around the world have not adopted mental health laws that would protect patients' rights, and in others patients are not informed of their rights. The use of psychiatry for political purposes is not uncommon in many parts of the world, although it is rarely used to the extent as in the Soviet Union in past years. The committee is actively seeking ways to facilitate the work of the newly emerging independent psychiatric organizations in preventing the recurrence of these practices in the future.

The committee has written to over 150 pharmaceutical companies to obtain copies of their international guidelines for drug trials and testing in other countries. There have been allegations in the past that the standards in effect in the United States are not always used in other countries, and the committee is looking into these allegations.

The committee has organized a symposium for the APA annual meeting: "Psychiatric Abuse, Abusers, and Scientific Exchanges." The symposium will include presentations on Romanian psychiatry, the politics of Soviet psychiatry, an analysis of the Soviet psychiatric literature, and issues related to scientific exchanges with individuals involved in psychiatric abuse.

The *Task Force on Conflict Resolution,* R. Curtis Bristol, M.D., chairperson, has organized an innovative workshop for the APA annual meeting, and the council is pleased and honored to have Ambassador Max Kampelman present "Conflict Resolution and the World of Diplomacy," in which he will discuss his experience as head of the U.S. delegation in bilateral negotiations on nuclear and space arms in Geneva.

The task force is also seeking outside funding for a 3-year collaborative study designed to produce a theory defining and explaining the process of conflict resolution. To further theoretical development in the field of conflict resolution, the task force plans to establish a scholars' working group of social scientists, which initially will assess and synthesize current theoretical contributions and then develop a theory to expand on the process of conflict resolution. This task force intends to publish a document produced by the collaborative effort of its scholars working group, which is meant to pave the way for further debate and for testing of the theory in practical application, both internationally and nationally.

The *Task Force on the Psychosocial Aspects of the Middle East Peace Process,* George Tarjan, M.D., chairperson, will probably be reactivated in light of the current developments in the Middle East and numerous requests by colleagues and others in that part of the world for APA's assistance in bringing individuals together as it has done in the past. The council has asked for additional appointments to the task force so that these requests can be examined, and a proposal to the APA leadership might be forthcoming. After a specific proposal is approved by the APA Board of Trustees, outside funding would be required before any substantive project could be undertaken.

The council has discussed issues related to the WPA and is trying to find ways to help strengthen that organization in a way that would benefit all of its members, including APA. Many organizations around the world look to APA for assistance in areas that might otherwise be handled by the WPA, and if APA is to remain a member of the WPA, it should do everything possible to ensure the viability of the WPA's work. The council has recommended that the Task Force on Liaison with the WPA, Eugene Feigelson, M.D., chairperson, be disbanded and has taken over the charge to that task force.

In addition, the council is planning ways to further its collaboration with international allied organizations, and in the future it will invite representatives of different international organizations to make presentations about their work at the September meeting of the council. There is much that we can learn from each other, and the council believes collaboration of this sort will be very valuable.

The council appreciates the assistance APA members have provided to colleagues in the newly emerging democracies of the world through the APA Office of International Affairs. It is looking for ways to involve the APA membership at large in international collaboration, and members are encouraged to contact the office with any suggestions about how this goal might be furthered.

# The Council on Medical Education and Career Development

Jerald Kay, M.D., Chairperson

The council has overall responsibility for all issues and efforts related to medical education, both for psychiatrists and, where appropriate, other physicians. Its responsibility includes promoting quality education and training for medical students and residents, as well as continuing education activities for practitioners. It is involved with activities related to subspecialties and special areas of clinical interest, such as child and adolescent psychiatry, consultation-liaison psychiatry, and administrative psychiatry. In collaboration with its 17 components, other APA components, and related psychiatric organizations, the council has been very active in the recruitment of medical students into psychiatry.

In addition, the council also has primary responsibility for implementing and monitoring the APA continuing medical education (CME) requirement of the membership in order to promote the highest quality of psychiatric care and to encourage continued professional growth of psychiatrists.

The council convened a meeting of representatives of the American Board of Psychiatry and Neurology, Inc. (ABPN), the Residency Review Committee for Psychiatry (RRC), and the APA Committee on Graduate Education and Commission on Subspecialization to address issues related to subspecialty fellowship training programs. The group focused its discussion on the need for accreditation of all subspecialty fellowship programs and for certification of persons completing such programs. To continue the dialogue, the group will meet again in September 1992 during the APA component meetings.

The *Committee on Administrative Psychiatry,* Stephen Rachlin, M.D., chairperson, reported the results of the oral portion of the certification examination in administrative psychiatry, held on May 11, 1991, during the annual meeting in New Orleans. Of the eight candidates examined, two passed and have been certified, four "conditioned," and two failed. Dr. W. Walter Menninger was named the recipient of the 1992 Administrative Psychiatry Award.

The *Committee on Consultation-Liaison Psychiatry and Primary Care Education,* Fawzy I. Fawzy, M.D., chairperson, proposed establishment of a subcommittee on psychiatric aspects of life-sustaining technology to define the contribution psychiatry can make to the understanding of patient, family, and caregiver attitudes and behavior toward the critically and terminally ill. Further, the subcommittee will identify the proper role of psychiatry and psychiatrists, in particular, in dealing with the clinical and ethical issues in the care of such patients.

The committee has submitted an application for added qualifications in consultation-liaison psychiatry and primary care education, which is being reviewed by the APA Commission on Subspecialization. The committee continues to strengthen its liaisons with the Society of General Internal Medicine and the American Academy of Family Practice, and it is collaborating with Dr. Robert Hales on a proposed project to develop the *DSM-IV* version for primary care.

The *Committee on Graduate Education,* James H. Shore, M.D., chairperson, reported on its newly defined liaison with the APA Commission on Subspecialization and its collaborative work to evaluate new subspecialty proposals and the potential impact on educational issues for postgraduate training resources in psychiatry. It has sought an expanded dialogue with the ABPN and the RRC concerning the process and outcome of accreditation of new subspecialties and certification of individuals completing them. The status of geriatric, addiction, and forensic psychiatry was carefully reviewed. The committee supports the strongest possible emphasis on research training for each new subspecialty.

Residents' concern about the risk of HIV infection through needle stick was addressed by the committee. The Accreditation Council for Graduate Medical Education is developing guidelines for disability insurance. The committee will disseminate these guidelines and review the issue with the Committee of Residents and Fellows.

The recruitment of medical students into psychiatry was fully addressed, and presentations were given by the presidents of the American Association of Directors of Psychiatry Residency Training and the Association of Directors of Medical Student Education in Psychiatry. The committee will work jointly with the Council on Medical Education and Career Development to stimulate a national dialogue and to pursue identified initiatives for recruitment.

The *Committee on Continuing Education,* Pauline Langsley, M.D., chairperson, reported on the new Accreditation Council for Continuing Medical Education "Essentials" for accreditation as a cosponsoring organization for CME programs. The Essentials require that APA, to continue as an accredited cosponsor, be actively involved in needs assessment, faculty selection, and evaluation for all APA-cosponsored CME programs.

The committee proposes that APA, through coordination in the Office of Education, solicit and designate annual meeting courses which provide an overview of psychiatry and assist members in acquiring board certification.

The *Committee on the Impaired Physician,* Malkah T. Notman, M.D., chairperson, has developed "Guidelines for Mental Health Services for Medical Students and Residents." If this document is approved, it will be submitted for publication to *Academic Medicine.* Production of an educational videotape on physicians' impairment, which will use interviews of physicians and patients, is underway.

A subcommittee of the committee has been formed to develop operational definitions of impaired judgment, incompetence, and negligent behavior of physicians. This subcommittee will report back to the committee in May 1992. It is also working with the Commission on AIDS and the Committee on Gay, Lesbian, and Bisexual Issues on HIV infection in physicians, with an emphasis on the biopsychosocial dimensions of impairment.

The *Committee on Medical Student Education,* Carol A. Bernstein, M.D., chairperson, continues to address issues affecting graduate medical education and the substantial decrease in the recruitment of medical students into psychiatry. The committee discussed the need for coordinated and sustained initiatives in this area and specifically focused on the necessity of obtaining support from departmental chairpersons. In this regard, the committee felt that each department of psychiatry should be encouraged to identify a director of medical student education who is at least half-time. It plans to conduct an informal telephone survey of medical schools that have been most effective and least effective in recruiting students into psychiatry over the past 5 years, to help clarify salient recruitment variables.

Specific recruitment activities include coordination of the distribution of the APA Division of Public Affairs' film series to every medical school in the country. The films will provide guidance to local resident groups and encourage them to discuss career possibilities in psychiatry with medical students. In addition, the committee will be promoting the development of medical school senior-year electives within psychiatry residency programs, in collaboration with the Association of Directors of Medical Student Education in Psychiatry and the American Association of Directors of Psychiatry Residency Training. The committee will continue to send representatives to the annual conventions of the American Medical Student Association and the Student National Medical Association, which remain excellent opportunities to meet and speak with students regarding careers in psychiatry.

The first issue of *Lucid Associations,* a medical student newsletter, was distributed to all Medical Student Members of the Association. Committee members will also be writing a series of articles for the *New Physician* (published by the American Medical Student Association), for the *Psychiatric Residents' Newsletter* (published by the Committee of Residents and Fellows), and for *Psychiatric News* to highlight issues relevant to medical students and medical student education.

In May 1991 the recipients of the first Nancy C.A. Roeske, M.D., Certificate for Excellence in Medical Student Education were honored at the third annual Medical Student Day luncheon. There were 48 recipients of the certificate; 11 were voluntary faculty and 37 were salaried, and they represented medical schools from every region of the country. The committee reviewed 61 applications for the 1992 certificate, and those selected will receive their certificates at the annual meeting in May 1992.

Medical Student Day and the annual luncheon for medical students, residents, and training directors continue to be enormous successes at the annual meeting. Over 250 people attended the 1991 luncheon, including medical students, residents, Roeske certificate recipients, and distinguished APA leaders. If outside funding can be obtained, the fourth annual Medical Student Day luncheon will be held in 1992.

To increase its effectiveness, the committee plans to work closely with other organizations, such as the Association of Directors of Medical Student Education in Psychiatry, the American Association of Directors of Psychiatry Residency Training, and the Association for Academic Psychiatry, which are also dedicated to recruitment and education of medical students.

The *Committee of Residents and Fellows,* Mary Marshall Overstreet, J.D., M.D., chairperson, continues to address the educational aspects of a wide range of issues affecting psychiatry and psychiatric education and training. These issues include student loan indebtedness, prescribing privileges for psychologists, access to health care, and the resource-based relative value scale (RBRVS) reimbursement plan. The committee is working with the Division of Government Relations and the other APA resident groups to assist residents in planning individual discussions on these political issues with their respective Congressional representatives during the APA annual meeting in May 1992.

The committee is especially concerned about the lack of both formal ethics instruction in general and role modeling for specific situations, such as interacting with third-party payers. Additionally, the potential adverse impact on psychiatric education that could emerge from the trend toward subspecialization within the field is being discussed with other concerned components.

Recruitment of medical students into psychiatry also continues to be of great concern. The committee discussed ways in which residents can become more active in recruitment efforts, such as improving liaison with medical colleagues, providing role models and education to medical students early in their training, and continuing to demystify and demythicize the work of psychiatry.

The committee continues to write and publish the *Psychiatric Residents' Newsletter* and serves on the editorial board of the *Jefferson Journal of Psychiatry.*

The *Steering Committee, Psychiatric Knowledge and Skills Self-Assessment Program VI (PKSAP VI),* Gordon Strauss, M.D., chairperson, reported that all three modules (A, B, and C) are available as a package. Each module provides 48 hours of category I CME credits, and there are no deadlines for submission of answer sheets for central scoring. Program participants will receive confidential scoring (through assignment of an individual code), a CME certificate, a critique, and a reference book.

The *Task Force on Educational Activities for Diagnostic Systems,* Michael Fauman, M.D., chairperson, completed the initial diagnostic practice survey and analysis of the implementation of *DSM-III-R* by psychiatrists. The survey was sent to a random sample of 931 APA members, and there was a 64% response rate (N=596). On the basis of the data collected, the task force concluded that a follow-up survey is needed to explore the different subpopulations of responders to the first survey and to help design additional educational materials.

The task force feels that its name is cumbersome and does not accurately reflect the specificity of its functions. It has recommended that its name be changed to the Task Force on Diagnostic Education.

The task force continues its collaborative work with the Task Force on DSM-IV and the Committee on Diagnosis and Assessment.

The *Task Force to Facilitate Communication Between APA and ABPN,* Rodrigo Munoz, M.D., chairperson, has focused on increasing the number of minority directors on the ABPN Board of Directors and the number of minority physicians who serve as examiners. It has also renewed its efforts to obtain ABPN assistance in creating APA-sponsored courses for physicians who are applying for certification. The task force feels that the process will be expedited if examiners are permitted to participate in APA courses.

The *Task Force on Post Residency Fellowship Programs,* George Pollock, M.D., Ph.D., chairperson, completed its work and prepared an appendix of fellowship programs, which accompanies the *Directory of Psychiatry Residency Training Programs* (1). Further, the task force recommended that APA convene a meeting of representatives from APA, the ABPN, and the RRC to discuss accreditation of subspecialty fellowship programs and certification of individuals who complete such training.

The *Task Force on Recertification,* Joe Tupin, M.D., chairperson, completed its charge "to study existing and proposed recertification activities of other medical specialty organizations" and has developed recommendations for recertification programs in psychiatry. The Board of Trustees accepted the task force's final report and its recommendation that the task force be disbanded and a permanent standing APA component be established to work with ABPN representatives on developing educational programs to help members prepare for recertification and initial certification.

The *Committee of Young Psychiatrists,* Mary Ellen Foti, M.D., chairperson, continues to be concerned about retention of APA members as they advance from Member-in-Training to General Member status. It is working with the Committee on Membership to develop studies that may provide data on the extent of the problem and its causes. Additionally, the committee has developed a model survey of young psychiatrists that will provide data on practice patterns, professional concerns, and other issues of concern to "young psychiatrist" members of the Association (those who are younger than 40 years or have practiced less than 5 years).

The committee believes that the primary concerns of young psychiatrists relate to early career development, and this issue will be the focus of a workshop and breakfast session at the annual meeting in May 1992.

Through the efforts of Drs. Paul Putman (Delegate) and James C.V. Chou (Alternate Delegate), the committee remains active in the Young Physicians Section of the American Medical Association.

The *Work Group on Recertification,* Gordon Strauss, M.D., chairperson, convened for the first time in September 1991. The work group focused its discussion on the ABPN's tentative plans for establishing recertification and the need for APA to make recommendations that will appropriately affect the ABPN's final plan.

The *Subcommittee on Certification,* Gerald Melchiode, M.D., chairperson, convened for the first time in September 1991. The subcommittee discussed various ways APA could help its members prepare for certification and plans to develop information on useful sources of assistance.

The *APA/Mead Johnson Fellowship Selection Committee,* Stuart Keill, M.D., chairperson, selected the 1991–1992 APA/Mead Johnson Fellows during its June 1991 meeting, and there were no major discrepancies in the ranking among the members of the committee. Forty-two nominations were received, from which 15 fellows were selected. It was agreed that the selection process would remain substantially as is.

The committee reviewed the process for inviting nominations and agreed to make certain refinements to the solicitation process.

The *Selection/Advisory Committee of the APA/NIMH Minority Fellowship Program,* Charles Pinderhughes, M.D., chairperson, selected seven of the 18 residents who applied for the 1990–1991 fellowship program. In addition, the committee selected four alternates and named five 1989–1990 fellows as trainee consultants.

The committee sought approval to publish, as a monograph, the proceedings of the 1986 symposium "Ethnic Difference: Do You Amend Your Therapeutic Approach?"

The *APA/Burroughs Wellcome Fellowship Selection and Program Committee,* Roger Peele, M.D., chairperson, reviewed 50 nominations for the 1991–1993 program and selected 10 new fellows.

On behalf of the Burroughs Wellcome Company, Mr. Jerald Breitman presented a check for $115,000 for financial support of the fellowship at the May 1991 meeting of the Board of Trustees. A reception was hosted by the Burroughs Wellcome Company for current and former APA/Burroughs Wellcome (formerly Falk) Fellows, representatives of the Maurice Falk Medical Fund, and APA members and staff who have been involved in the program.

The research symposium held during the September component meetings featured the presentations "Developing a Risk Profile in Vietnamese Amerasians" (Alice Mao Brams, M.D., Chief Resident, Division of Child Psychiatry, Cullen Bayou Place, Baylor College of Medicine) and "Psychiatric Research Opportunities at NIMH" (Samuel Keith, M.D., Acting Deputy Director of NIMH and Acting Director of the Division of Applied Services Research). In addition, a current APA/Burroughs Wellcome Fellow (James Hudziak, M.D., Washington University School of Medicine) presented "A Survey of Obstacles to Doing Research as a Psychiatric Resident."

The fellows discussed the need for continued participation of APA/Burroughs Wellcome Fellows in APA, both at the national and local levels, so that they can retain and practice the skills acquired during the fellowship. The program continues to be a highly valued channel for the training of tomorrow's leaders in psychiatry.

# The Council on National Affairs

### Fred Gottlieb, M.D., Chairperson

This council is responsible for matters of national interest to psychiatry and the patients it serves. Social and health-related issues that adversely affect underrepresented and underserved groups in the general population and within the profession elicit particular attention by the council. The council works closely with representatives from the Assembly and other APA components and with APA staff. The 11 components that specifically report to the council include those representing the six designated minority groups, the Committee on International Medical Graduates, and four components dealing with other relevant national issues: psychiatry's abuse and misuse, nuclear issues, disasters, and the relationship of psychiatry and religion.

Dr. James Thompson chaired the May meeting, during which the council approved a resolution thanking Dr. Lindbergh Sata, whose council tenure was ending, for his leadership and wise counsel.

In September the council initiated reconsideration of its past, present, and potential contributions to the profession, our patients, and the organization. The council has been an important locus, in which advocacy for the temporarily unempowered has been marshalled and in which innovative solutions have been sought and valued. Council members stressed that in addition to responding to issues referred to it, the council should initiate activities, reaching out to and nurturing its components with ideas, as well as advice and encouragement. The council plans to meet in February to continue reevaluating its structure, functions, and goals. It is aware of the risk of being considered parochial, when in fact its interests are flexible and far-ranging, in keeping with its charge. The council's liaison to the Board of Trustees suggested that a multicultural curriculum for use in residency training programs may be more integrative than several discrete culturally oriented curricula. Apparently Dr. Leah Dickstein is attempting to devise such a multicultural curriculum, based on proposals from various components of the Council on National Affairs.

When it met with the Joint Commission on Government Affairs, the council requested ongoing updating on legislation about uniform licensure. The council also urged that APA use all Congressional hearings (e.g., Supreme Court nominations) as opportunities to present relevant APA policies, and the council noted that national health insurance is an issue of particular salience for minority and underserved populations, as well as for *all* Americans interested in national affairs.

During the fall component meetings, a representative of the Steering Committee on Practice Guidelines spoke to the council about the development of practice guidelines and asked the council if it was interested in having a formal liaison to the steering committee. The council emphasized the importance of heterogeneous input and representation, among both the reviewers and the work groups, from the many sectors of psychiatry.

A member of APA's Resource Development Committee spoke to the council about a proposed nonprofit foundation that would seek to link the major U.S. minority medical societies, the U.S. Department of Health and Human Services, and the Merck Foundation to address the continuing problems in service delivery, especially to many minority patients. The Urban Health Alliance plans to fund worthwhile minority projects—e.g., in physician recruitment and professional education, clinical studies, illness screening, and patient and family education—and to be involved in appropriate public policy activities.

Following are reports on the activities of the components under the Council on National Affairs.

The *Committee on Abuse and Misuse of Psychiatry in the U.S.,* Ledro R. Justice, M.D., chairperson, discussed the Joint Reference Committee's recommendations on the draft of "Misuse and Abuse of Psychiatry in the U.S.: A Definition and Discussion," particularly the definition of abuse. The committee will review other comments received from members who attended the fall meetings and will then revise the paper. While the focus of the draft was to stimulate discussion of abuse within the psychiatric community, APA has yet to formulate a position statement. The committee is preparing a position statement on abuse and misuse of psychiatry, beyond the current draft.

The committee discussed its mission and agreed that it also should handle individual cases within the guidelines of the committee's charge. It will continue to review cases sent to APA, collect additional information as needed, and report findings to the Medical Director and APA counsel. The council asked that the committee obtain follow-up on the results of prior referrals. The committee also agreed that it would continue to stimulate discussion about abuse and misuse of psychiatry, focus on prevention, and investigate organized systems in which abuse and misuse can occur.

The committee met with Dr. Jeremy Lazarus, chairperson of the Ethics Committee. Examples of individual ethics violations and institutional abuse were discussed in order to compare and contrast definitions and concepts. The consensus was that the work of the two committees overlaps on occasion. It was stressed that the Ethics Committee considers only individual matters and that it has the ability to perform on-site assessments and obtain legal counsel. Dr. Lazarus suggested that a newsletter would be useful in educating psychiatrists and nonclinicians and in eliciting feedback on concerns about abuse and misuse. Dr. Lazarus offered the use of the Ethics Committee's newsletter.

The committee also met with the Committee on Gay, Lesbian, and Bisexual Issues to discuss some of the latter's concerns. Apparently some psychiatrists attempt to change the sexual orientation of patients by means of "reparative therapy," which is based on the invalid assertion that homosexuality is a mental illness. There was some discussion of clinical and treatment issues, including the importance of clinical neutrality and absence of stigma and prejudice on the therapist's part. (See also the discussion of this issue in the report of the Committee on Gay, Lesbian, and Bisexual Issues.)

To determine the usefulness of contacting patient advocacy groups, the committee met with Mr. John Blamphin of the APA Division of Public Affairs. Mr. Blamphin explained how complaints are generally sent to and distributed within APA. Most complaints received by his office would not be referred to this committee. He suggested that the committee not encourage advocacy groups to send complaints but saw no problem in the committee's informing these groups that the committee exists. He also suggested that the committee write to Ms. Laurie Flynn of the National Alliance for the Mentally Ill.

When the committee discussed the decrease in the number of American medical students entering psychiatry, it concluded that such a decrease in the number of psychiatrists poses a risk for abuse of psychiatry because it could lead to further limitations in the adequate treatment of patients who can best afford treatment and less adequate treatment of those less able to pay.

The *Committee of American Indian, Alaska Native, and Native Hawaiian Psychiatrists,* Albert Samuelson, M.D., chairperson, was formerly the Committee of American Indian/Alaskan Native Psychiatrists. Native Hawaiian psychiatrists sought to be part of this committee, and the committee welcomed this addition. The committee asked that Native Hawaiian psychiatrists be represented on the committee and that the committee's name be changed. "Alaskan Native" was changed to "Alaska Native" because "Alaskan" could refer to anyone born in Alaska, whereas "Alaska Native" refers to the ethnic group native to the state. For the same reason, "Native American" could be taken to mean anyone born in America, whereas "American Indian" refers to the ethnic group. By contrast, the Hawaiian psychiatrists chose "Native Hawaiian."

The American Medical Association (AMA), through Project USA, presently offers physicians the opportunity to work for brief periods on reservations in underserved areas. Travel, malpractice insurance, and small stipends are provided. Project USA has not yet offered psychiatrists a similar opportunity to serve. The committee recommends that APA explore with the AMA and the Indian Health Service the feasibility of offering APA members a similar opportunity to serve in public psychiatry through Project USA and other programs. The council suggested that the committee discuss this with the AMA Section Council on Psychiatry and the APA delegate to the AMA.

The committee continues to be concerned about the severe problem of alcohol dependency among Indian people, which has catastrophic health and social consequences. The report of the U.S. General Accounting Office on addiction services on reservations reinforces the pressing need to strengthen these programs. The committee recommended that the Council on Addiction Psychiatry establish liaison with the Indian Health Service and offer APA resources and expertise for resolution of this critical health problem. The council also recommended that the committee discuss this matter with the Council on Addiction Psychiatry.

The *Committee of Asian-American Psychiatrists,* Francis Lu, M.D., chairperson, is involved in a number of projects: recruitment of Asian-American psychiatrists for membership in APA, implementation of the annual Asian/Asian-American Award, facilitation of communication with allied Asian-American psychiatric groups and the Pacific Rim College of Psychiatrists, and outreach to Asian-American psychiatrists and residents at the annual meeting through the component workshop, reception, and breakfast meeting with residents. Given the rapid increase in the Asian-American population, the committee believes its charge remains important to APA and the mental health of Asian-Americans.

The newest charge to the committee, approved in 1990 by the Board of Trustees, is to focus on ways to increase Asian-American membership in APA. This charge is important for APA not only because it could increase the number of members but also because it could increase Asian-American psychiatrists' participation in APA activities. The committee developed three recruitment strategies: recruitment with help from allied organizations, recruitment of Asian-American psychiatric residents, and recruitment of Asian-American medical students interested in psychiatry. All three strategies would involve collaboration with the Committee on Membership and the Office of Membership. The committee's detailed recruitment strategies were presented to the Joint Reference Committee as potential models for replication in other parts of APA.

The committee will present the Asian/Asian-American Award for the first time at the May 1992 annual meeting. The 1992 awards will be presented to Drs. Tsung-Yi Lin and Lindbergh S. Sata. Kun-Po Soo, M.D., Ph.D., of Taiwan, donated $50,000 to endow this award. The committee developed a brochure publicizing the Asian/Asian-American Award along the lines of the one for the Solomon Carter Fuller Award. The council approved the publication of this brochure, subject to approval by the Joint Reference Committee and the Board of Trustees.

The committee prepared a proposal for a new V code, "psychoreligious or psychospiritual problem," which it sent to the Committee on Religion and Psychiatry for its review.

On May 6, 1989, APA and the Pacific Rim College of Psychiatrists cosponsored the First International Symposium on Psychiatric Research, which was organized by the Committee of Asian-American Psychiatrists. The committee has now finished editing the proceedings of that symposium and, with the council's approval, will send it to the APA Editorial Review Panel for its consideration, with a view to publication by APA.

The *Committee of Black Psychiatrists,* Robert T.M. Phillips, M.D., chairperson, revised the language of its charge to better reflect its work. After some small modifications, the revised charge was accepted and submitted to the Board of Trustees.

In previous meetings the committee had discussed drafting a position statement on racial/ethnic harassment. Committee members think that more background work is needed. Committee member Dr. Sheree Dixon and Ms. Alison Bondurant of the APA Office of Minority/National Affairs agreed to research APA's efforts regarding this issue. If the committee finds that APA has taken an adequate position against racial harassment, it will not pursue the matter.

Like other components of the council, this committee wants to become more involved in APA efforts to recruit members. To expedite the process, Dr. Phillips met with the Committee on Medical Student Education, and committee member Dr. Joshua Calhoun met with the Committee of Residents and Fellows and the Committee of Young Psychiatrists. All three committees were receptive to the idea of collaboration with the Committee of Black Psychiatrists.

In response to material from APA's Division of Government Relations, Dr. Phillips encouraged committee members to write to their state legislators and appropriate staff of the U.S. Department of Defense to express opposition to legislation that would give prescribing privileges to psychologists in the military.

The committee selected Dr. Gloria Johnson Powell for the 1992 Solomon Carter Fuller Award.

The *Committee on Gay, Lesbian, and Bisexual Issues,* Richard A. Isay, M.D., chairperson, would like to have better links with national and international groups concerned with gay and lesbian rights and health issues. For instance, the International Lesbian and Gay Association helps members achieve rights worldwide by focusing public and government attention on lesbian and gay rights, by supporting programs, and by exerting diplomatic pressure. It also represents lesbian and gay rights in the work of international bodies, such as the United Nations, and is campaigning for Amnesty International to consider lesbians and gay men imprisoned because of their sexuality as prisoners of conscience. The committee decided not to ask for authorization to apply for membership in the International Lesbian and Gay Association; instead, many committee members who are members of the Association of Gay and Lesbian Psychiatrists will urge that organization to join the International Lesbian and Gay Association.

In September 1990 the committee proposed a position statement on the right to privacy. At the council's suggestion, the committee asked other APA components to review the statement, which it then revised. The council presented the statement to the Joint Reference Committee in June 1991. The Joint Reference Committee referred the proposed position statement on the right to privacy back to the Council on National Affairs and to this committee, with suggestions for further revisions. The committee discussed the Joint Reference Committee's suggestions and revised the position statement, which was approved by the council and then by the Joint Reference Committee in October 1991: "Be it resolved that the American Psychiatric Association supports the right to privacy in matters such as birth control, reproductive choice, and adult consensual sexual relations conducted in private, and supports legislative, judicial, and regulatory efforts to protect and guarantee this right."

The committee discussed how to deal with books that contain explicitly antihomosexual attitudes. The committee cited the new book by Joseph Nicolosi, *Reparative Therapy of Male Homosexuality.* Dr. Isay has talked with Dr. Marshall Forstein (Association of Gay and Lesbian Psychiatrists), Michael Siever (American Psychological Association), and Gary Lloyd (National Association of Social Workers) about organizing some action. Dr. Forstein discussed this further at the annual meeting of the Association of Gay and Lesbian Psychiatrists.

The committee spoke with Dr. Abram Hostetter of the Committee on Special Benefit Programs regarding insurance for domestic partners.

The committee suggested a task force, possibly under the Council on Children, Adolescents, and Their Families, to deal with the problem of suicide among gay and lesbian youth.

The *Committee of Hispanic Psychiatrists,* Eduardo R. Val, M.D., chairperson, reviewed the text and sketches for the comic book *Hablemos,* first published in English under the title *Let's Talk About It.* Copies were made available at the minority/national affairs exhibit booth at the annual meeting in May. In December 1990 the Board of Trustees authorized this committee to seek outside funds for a data base on Hispanic mental health and social services. This data base would include information on psychiatrists, special psychiatric societies, and national organizations. At the committee's fall meeting, Dr. Juan Ramos from the National Institute of Mental Health (NIMH) informed the committee that the current NIMH administration approved $25,000 for this project, which will be housed in the APA Office of Research. Dr. Ramos indicated that funds for the second phase of the project would be available in 1993.

The committee discussed the criteria and procedures for the Simon Bolivar Award in response to a letter from a committee member. After a lengthy discussion, the committee agreed that 1) the committee will consider suggestions from any APA member and 2) a committee member can suggest and endorse a candidate by giving specific reasons and submitting the candidate's curriculum vitae to the committee chairperson. Last May the committee selected Dr. Raquel Cohen for the 1992 Simon Bolivar Award.

Another issue the committee found worrisome is the decrease in the number of medical students selecting the specialty of psychiatry. Besides financial considerations, the committee felt that one reason for this decrease is that departments of psychiatry give less direct faculty time to medical students because of the pressure to increase departmental revenue through activities other than teaching.

The *Committee on International Medical Graduates,* Richard Balon, M.D., chairperson, was pleased that the proceedings of the first three international medical graduate (IMG) regional meetings have been made available to interested parties. These meetings were convened to help IMGs bridge language and cultural gaps, understand the theories underlying the American psychiatric service systems and social issues germane to mental health care, and establish a network for IMGs' emotional and professional support. Because of the favorable reception of these proceedings, the committee sought authorization to seek funds to publish the proceedings of the last two IMG meetings.

Some IMGs who are APA members feel that APA either does nothing for them or is not doing enough. The committee would like these and other members, as well as IMG psychiatrists who are not APA members, to know what APA has done and is doing to help them. To disseminate this information, the committee decided to resume publication of its newsletter, for which the committee received authorization to seek outside funds.

International medical graduates constitute 24% of the APA membership but are very significantly underrepresented within the APA component structure. This committee feels that IMGs on APA committees could present IMG problems pertinent to the committees' work better than could non-IMGs. At the council's request, Dr. Balon checked the current "Directory of Components and Staff" to see how many IMGs are on APA components. The dramatic disparity revealed by this count was presented to the Joint Reference Committee in October.

In the interests of attracting young IMG psychiatrists to APA, promoting cohesiveness within IMG groups, and recruiting and retaining members, the committee would like to hold a work-related reception for IMG residents in psychiatry and leaders of various ethnic groups during the 1992 annual meeting. To do this, the committee asked for authorization to seek outside funds.

The *Committee on Psychological Aspects of Nuclear Issues,* Stephen Shanfield, M.D., chairperson, received permission for non-APA publication of the papers presented at its 1990 symposium. The majority of the presenters were not APA members, and other papers not presented at the symposium will be added to the manuscript. The committee's bibliography on nuclear psychology was published in *PSR Quarterly: A Journal of Medicine.*

Part of the charge to this committee is to identify, evaluate, and synthesize emerging knowledge as the basis for educational approaches both within and outside the medical, behavioral, and social sciences and to disseminate information to the APA membership, selected strategic groups, and the general public. The committee was understandably distressed when its proposal for a symposium on nuclear issues for the 1991 annual meeting was initially rejected. This committee is concerned that its submission for the 1992 annual meeting might meet the same fate because nuclear issues do not fall under any designated rubric of the annual meeting program. The council suggested that the committee emphasize the appropriateness of this submission to the presidential theme.

The committee will also propose a symposium for the 1993 annual meeting. Presenters will include non-APA members, whose expenses the committee would like to defray. For this reason, the committee requested authorization to seek outside funds to pay for the transportation, lodging, and meals of five guest speakers. The council noted that the committee was setting an impressive example by planning a 1993 symposium now.

This committee and a representative from the Council on International Affairs are writing a curriculum on the psychology of international relationships; psychiatry residency training directors are the target audience. The committee would like to have this curriculum published promptly after it is completed, possibly as a curriculum or a bibliography that might be considered educational material suitable for submission directly to the Editorial Review Panel.

The *Committee on Religion and Psychiatry,* Richard Thurrell, M.D., chairperson, is concerned about the lack of representation of non-Judeo/Christian religious traditions and hopes that someone from these other faiths will be appointed to the committee in some capacity. Also, as a result of committee membership rotation, there is no one on the committee from a Jewish background. The committee hopes that this, too, will be rectified when appointments are made.

District branch activities in the area of religion and psychiatry remain a concern to the committee. District branches vary in their interest in and attention to this area of their patients' lives. The committee hopes to find ways to sharpen the district branches' concern about patients' spiritual lives and district branch relations with psychiatrically minded clergy.

The committee continues to be interested in cults of various sorts, particularly as they affect psychiatrically vulnerable persons. Dr. Ruth Barnhouse reports on satanic cults as developments warrant. Because the religious aspects of the "religion" of Scientology remain obscure to many committee members, members of the Association of Mental Health Clergy have promised, through informal liaisons, a report on Scientology as a religion.

Interested in its own history, the committee requested a report from long-time member Dr. William Grosch regarding the origin, initial efforts, and development of the committee.

The committee is still contemplating a brief, loose-leaf book containing numerous in-depth references for all psychiatrists in the vein of "What Every Psychiatrist Should Know About His or Her Patients' Religions." Such a compact volume would presumably inform and sensitize colleagues to the important role that religious belief, conflict, and aspiration might play in the life of a patient of a particular religious heritage.

The committee selected Dr. Paolos Mar Gregorios, Metropolitan of Delhi, for the 1992 Oskar Pfister Award.

The *Committee on Women,* Gail E. Robinson, M.D., chairperson, proposed a position statement on the care of female addicts who are pregnant or have just given birth, after consulting with other APA components. The Assembly and the Board of Trustees approved the statement, which recommended that APA take a leadership role in advocacy for these mothers and their children with departments of social services or their agencies legally responsible for the safety of these children.

In September the committee proposed reaffirmation of APA's position statement on abortion and recruitment and promotion of women and ethnic minorities in psychiatry. Council members questioned the need to reaffirm APA's position, and Dr. Robinson replied that there are efforts by some APA members to erode or even rescind this position statement. The council suggested that the committee use and expand the current statement, taking into account the attempts to erode it, and recommend APA action. In addition, the council suggested that the committee confer with other pertinent components.

After some revisions and consultation with other components, the committee presented its proposal for APA actions regarding reproductive rights, and the council voted to present it to the Board of Trustees as an urgent action item. The Board of Trustees approved this position statement and will forward it to the Assembly for its approval.

National statistics show that after more active recruitment of women into medicine, women now constitute 40% of medical school students. Many of these women specialize in psychiatry, particularly child psychiatry. Despite their numbers, very few are in senior academic positions. It is important to have women and ethnic minorities in senior academic and leadership positions so they can serve as role models, encourage younger women and ethnic minorities, and enhance the areas of study related to women's health, minority health, and parenting. Consequently, the committee recommended that the APA Board of Trustees take a leadership role in advocating recruitment of women and ethnic minorities for senior academic and administrative careers and the promotion of qualified women and ethnic minorities to leadership positions in these areas.

The committee will receive funding from Mead Johnson for an activity center at the 1992 annual meeting. The committee will schedule the following meetings at the center: 1) "What Is Involved in Becoming an APA Fellow (How to Keep Young Psychiatrists Involved in the APA)," 2) "Passing the Board Examinations," and 3) "How to Publish Papers."

So that the committee can remain up-to-date on issues important to women, each committee member will be responsible for a specific topic. The topics include abortion, parental leave, maternal/fetal rights and new reproductive technologies, patient-therapist sexual misconduct, violence against women, and sexual harassment.

The committee reviewed a memo from Dr. Jerald Kay, chairperson of the Council on Medical Education and Career Development, concerning the decrease in the number of American medical students entering psychiatry. The committee noted that this may particularly affect women: staffing may selectively hit areas involving women's mental health, women are more likely to practice in public psychiatry, and there is a disproportionate number of women in child psychiatry. The committee will write to Dr. Kay and will attach a list of suggestions about recruitment.

Dr. Viola Young Horbach, president of the Federation of Organizations of Professional Women, spoke to the committee about pending legal actions concerning the emotional repercussions for women of problems in the workplace. It was suggested that female physicians are in a relatively good position to fight back against discrimination in the workplace because they have the opportunity to go into private practice even if their academic careers are threatened because they speak out. It was also suggested that psychiatry help define the "reasonable woman" standard, which is the court's means of assessing what is reasonably perceived as sexual discrimination. It was suggested that it is important to increase the sensitivity toward these issues in regard to both patients and colleagues, that is, to speak out in communities about such discrimination, to develop policies regarding sexual harassment in the workplace, and to send letters to Dr. Louis Sullivan, Secretary of the U.S. Department of Health and Human Services, and Dr. Frederick Goodwin, Administrator of the Alcohol, Drug Abuse, and Mental Health Administration, asking them to comment on their policies regarding women.

The *Corresponding Task Force on Psychiatric Dimensions of Disasters,* Robert Pynoos, M.D., chairperson, has outlined actions recommended by the APA President in regard to the U.S. National Committee for the Decade of Natural Disaster Reduction. The task force has also asked each district branch to identify a liaison to the task force within the branch. Task force members have successfully collaborated with the American Academy of Child and Adolescent Psychiatry Work Group on Consumer Issues to compile relevant material regarding children and disasters. The task force's next step is to form a network of APA members to be part of a network for disaster response at the local, state, and national levels.

# The Council on Psychiatric Services

James T. Barter, M.D., Chairperson

The Council on Psychiatric Services is committed to furthering the delivery of high-quality psychiatric services. Psychiatrists, whether working in the private sector or the public sector, must constantly wrestle with an overburden of rules and regulations from governmental agencies, third-party payers, and managed care organizations. It is difficult to continue to promote easy access to quality care and services in such circumstances. The reports of the council and its component committees reflect psychiatry's commitment to our patients, our society, and ourselves.

The council has been especially concerned with the psychiatric practitioner, regardless of practice setting. The problems facing psychiatrists are similar and similarly difficult, whether they are working in the public or the private sector. The creation of the Consortium of Chairpersons of APA Components on Public Psychiatry last year was a direct consequence of the realization of the need to be more proactive in dealing with public psychiatry issues. A similar effort focusing on the psychiatric practitioner in private sector settings has begun. It is exquisitely obvious that the solo private practice psychiatrist is beleaguered, bothered, and bedeviled by equally troubling concerns. The council has intensified its interest in dealing with these issues and offers a forum for the views of the private practitioner to be explored, attended to, and disseminated throughout the governing structure of APA. The council has encouraged and recommended the appointment of more private practitioners to APA components to enhance their ability to be heard and involved in policy formation. Structural changes have been suggested, including creation of additional components and reorganization of existing components. These ideas are being actively debated and considered. Last year was challenging and productive, as reflected in the following reports of the component committees and task forces. Next year should be no less.

The *Consortium of Chairpersons of APA Components on Public Psychiatry,* J. Frank James, M.D., chairperson, was established by the Board of Trustees in December 1990 and charged with identifying deficiencies in the delivery of care to groups with special needs and with documenting existing or hypothetical models that address such deficiencies in a cost-effective and clinically sound manner. Accordingly, the group is to prepare information for the APA leadership that may be used for advocacy and other purposes to benefit the psychiatric care delivery system. The consortium reports to and is accountable to the Council on Psychiatric Services.

The consortium includes the chairpersons of the following components: Committee on State and Community Psychiatry Systems, Task Force on the Homeless Mentally Ill, Corresponding Task Force on Geriatric Psychiatry in the Public Mental Health Sector, Committee on Chronically Ill and Emotionally Handicapped Children, Committee on the Chronically Mentally Ill, Committee on Psychiatric Disability and Rehabilitation, the State-University Collaboration Project, Assembly Committee on Community Psychiatry, and Assembly Committee on Public Psychiatry. Others will be invited to participate with the consortium.

The consortium has stressed the need for access to treatment and care for the severely mentally ill and the need to ensure such access in any national health care plan that may emerge. The consortium has also called attention to the need to involve more psychiatrists in the public sector and, hence, the need for incentives for psychiatrists to seek positions or volunteer services in the public sector and recognition of their efforts. Over the past year the consortium has generated many recommendations, which are now in various states of study, approval, and implementation. Recommendations that have been approved by the Board include the following.

1. Advocacy of access to and reimbursement for care for the severely mentally ill that is equal to that for other psychiatric and medical patients.
2. Promotion of psychiatric diagnosis and treatment as an essential component of any rehabilitation program for severely mentally ill persons.
3. Encouragement of public mental health programs to develop ways in which psychiatrists may volunteer or provide services, teaching, supervision, or advocacy.
4. Encouragement of psychiatrists to work in or volunteer some time in public psychiatric programs.
5. Addition of work experience or contribution of time in a public psychiatric program as a category to be considered in decisions on eligibility for APA Fellowship.
6. Inclusion in the next biographical survey, or sample survey, of items intended to clarify amounts of time psychiatrists work or volunteer in public mental health programs.
7. Encouragement of the district branches to develop mechanisms for recognizing those who provide or volunteer direct services to the severely mentally ill.
8. Exploration with pharmaceutical companies of the possibility of supporting programs for recognizing psychiatrists in the public sector, such as a fellowship in an academic center, a traveling or visiting scholar award, or a research sabbatical.

The following are under study by other components.

1. APA promotion of standards for residency training that include a significant training experience in a public health program to prepare residents for career opportunities in public psychiatry (Council on Medical Education).
2. APA encouragement of public mental health programs to develop a forgiveness or "buy-out" program for trainee indebtedness in exchange for a period of service in a public mental health program (Committee on Residents and Fellows).
3. Focus on public psychiatry issues by the biennial State Legislative Institute and Public Affairs Institute (Joint Commission on Government Relations).
4. Assembly exploration of ways of giving greater representation to public sector psychiatrists in the Assembly (Assembly Committee on Public Psychiatry).

The Assembly approved the consortium's recommendation that all district branches be encouraged to include representation of public psychiatry on their executive councils.

Under further study by the council and consortium are the following.

1. APA leadership in developing a national consortium of provider and consumer groups that could, in the public sector context, further interdisciplinary collaboration in care delivery, develop greater collaboration with consumer groups, explore remedies for present deficiencies in public psychiatric services, improve access to care, and explore options for formulation of a national health care plan.
2. APA encouragement of state and other organized mental health agencies to adopt standards of practice for psychiatrists.
3. APA encouragement of state agencies to provide an opportunity for public psychiatrists to spend some time in academic settings in exchange for trainee supervision or other service.

The *Committee on Private Practice,* Boris Rifkin, M.D., chairperson, has stated that its highest priority is survival of the private practitioner. The committee and council appreciate the frustration and confusion faced particularly by the solo office practitioner wrestling with changing practice patterns generated by managed care, Medicare regulations, codes and reimbursement procedures, and the anticipated physician payment scale that will emerge from work on the resource-based relative value scale. Like "public psychiatry," "private practice" has a definition that varies according to context, and clarification of types of practices in the "private practice sector" is needed. Much of the work of the APA components and offices has an impact on the private practitioner—for example, on reimbursement, diagnostic clarification, reviews of various types of treatment, educational programs—but the relationship is not always easily recognized. Many private practitioners do not feel they have a strong voice in the deliberations of the Association. The council and committee are seeking ways to increase the visibility of the Association's commitment to private practitioners, to ensure greater private practice input to relevant APA components, and to organize reporting mechanisms and linkages in such a way as to ensure greater communication with private practitioners. The committee is studying the feasibility of developing a network with private practitioners in the district branches that would expand on the district branch private practice round-table that the committee has sponsored at the annual meeting for the past several years. Several proposals for change in the reporting structure for the committee and for linking the committee to other APA components have been discussed, and the council expects resolution in the coming year.

The *Committee on the Practice of Psychotherapy,* Marcia Goin, M.D., chairperson, looks forward to the National Institute of Mental Health workshop on cost-effectiveness of psychotherapy, which will take place during the spring of 1992. It participated in reviews of initial drafts of practice guidelines for eating disorders and anticipates having an opportunity to be continually involved in the review process. After reviewing summaries of industry-sponsored symposia presented at the 1991 annual meeting, the committee expressed concern that the programs rarely include discussion of psychodynamic psychotherapy as one of the treatment options for the topics presented (anxiety disorders, anxiety and the medically ill, etc.). The committee urged that APA require more scientific balance in these presentations and that the Scientific Program Committee maintain vigilance in this area.

The *Committee on the Chronically Mentally Ill,* Stephen Goldfinger, M.D., chairperson, made known its hope and support for a strong mental health focus within the new Alcohol, Drug Abuse, and Mental Health Services Administration, which will emerge from reorganization as the National Institute of Mental Health, National Institute on Drug Abuse, and National Institute on Alcohol Abuse and Alcoholism are moved under the auspices of the National Institutes of Health. The committee has continued to analyze data from the most recent APA biographical survey to capture information concerning the treatment of the chronically mentally ill. A report is anticipated during 1992. The committee is active in the consortium on public psychiatry, and many of the committee's views are reflected in the recommendations of the consortium.

The long-standing *Committee on Rehabilitation* and the *Task Force on Social Security Income and Social Security Disability Insurance,* both chaired by Arthur T. Meyerson, M.D., were disbanded during 1991. In recent years, the Committee on Rehabilitation wrestled with cuts in funding for treatment of adults with disabilities and the rewriting of the Social Security Administration's disability "listings" for adults and, separately, for children. The group addressed the availability of Medicare for psychiatric patients in nursing homes and addressed administrative cuts in day hospital programs for Medicare recipients by the Health Care Financing Administration. The new *Committee on Psychiatric Disability and Rehabilitation,* with a charge combining aspects of the two former components, is chaired by Kenneth Terkelsen, M.D. The new committee will address matters of national law and regulations affecting children and adults with disabilities, including physical disabilities complicated by psychiatric conditions. The committee will also monitor such matters as guidelines for provision of day treatment and other forms of rehabilitation services provided by psychiatrists. It will promote educational opportunities for psychiatrists in this area.

The *Committee on Psychiatric Services for Mentally Retarded and Developmentally Disabled Persons,* Ludwik S. Szymanski, M.D., chairperson, began its work this year on the shoulders of the previous Task Force on Psychiatric Services to Mentally Retarded Adults. That task force produced a report on the status of psychiatric services to mentally retarded adults and a series of recommendations concerning training, services of state departments of mental health and mental retardation, legislation and regulations, standards, and future areas of focus for APA. The initial plan of the new committee includes development of curricula, networking with a variety of organizations concerned with standards, emerging legislation and regulations, and education. It also hopes to maintain contact with the state departments of mental health and/or mental retardation.

The *Committee on Psychiatric Services in Jails and Prisons,* Henry C. Weinstein, M.D., chairperson, considered ways to increase attention to psychiatric services provided in these settings. The committee will encourage district branches to include representation of the corrections psychiatry field in their public psychiatry components. The committee is exploring the feasibility of a resource pool of individual experts, as well as materials that can be made available to psychiatrists, other interested professionals, and the public.

The *Committee on State and Community Psychiatry Systems,* Steven E. Katz, M.D., chairperson, continued to encourage APA district branches and areas to involve themselves in their states' efforts to develop annual comprehensive plans for psychiatric services in accordance with PL 99-660. State mental health systems are increasingly identifying children and adults with severe mental illnesses as their primary target population. Fewer than one-half of the states currently have full-time medical directors; only seven states require this position by law. The committee developed a job description for medical/clinical directors in state mental health authorities and hopes the description will assist state societies and district branches in persuading their states of the need for such positions. Noting the success of the State-University Collaboration Project, a program aimed at development of collaboration between academic and state psychiatric systems, the committee urged APA to ensure continuation of aspects of this project after the initial 3 years, funded by the Pew Memorial Trust, are completed. Along with the Committee on the Chronically Mentally Ill and others, this committee supported APA efforts to bring about the "unbundling" of the distribution and monitoring of use of clozapine by a single source. More recently, the committee has urged APA to press for financial support through state and federal programs to make clozapine available to those who will benefit from it.

The *Committee on Psychiatric Services in the Military,* Harry C. Holloway, M.D., chairperson, called to the attention of the council the development of mental health standards by the Department of Defense's Office of Health Affairs and prompted APA to offer expertise and advice. Many members of the committee were intensely involved in delivery of psychiatric services during and after Operation Desert Shield/Storm. They reminded the council that while the military effort in the Middle East is ostensibly over, the problems of military personnel and their families, including those of reserves, will continue to surface for some time. The committee hopes for psychiatry's continued interest in and willingness to assist military personnel and their families. Working with APA's Division of Government Relations, the committee provided valuable advice concerning CHAMPUS, the downsizing of the military force and military medicine, the Department of Defense pilot program for training psychologists to prescribe medications, and military and Public Health Service pay issues.

The *Committee on Veterans' Affairs,* Frederick Guggenheim, M.D., alerted the council that as Congress considers universal access to care, only one current plan mentions use of Department of Veterans Affairs (VA) hospitals. The committee urged the association to keep in mind how the VA system, particularly specialty care, can fit into plans for universal access to care. The committee monitored and commented on a number of reports of national significance, including two from the Institute of Medicine concerning research and use of resources and one from the VA Mission Commission, a federal commission studying the future structure of veterans' health care systems. The committee provides advice to the Division on Government Relations concerning education, budget, and pay issues, and in September the members of the committee conducted continued their annual visits to members of Congress.

The *Committee on the H&CP Service,* Gail Barton, M.D., chairperson, reaffirmed its commitment to serve mental health professionals in its 800-plus member facilities, as well as its commitment to distributing nearly 10,000 copies of *Hospital and Community Psychiatry* to professionals in those facilities. For 1992 the committee supports further expansion of the video and film library, which now includes more than 150 titles. Reviews and selection of videos included in this unique collection are made by Ian E. Alger, M.D. The 1992 "Video and Film Library Catalog," listing all the videos available for rent from the H&CP Service, is available on request. The Psychiatric Placement Service, established by the H&CP Service to help hospitals and other facilities find psychiatrists for vacant positions, receives continued support from the committee and staff. Since the program was established in 1986, 72 psychiatrists have found new positions through this program.

The *Institute on Hospital and Community Psychiatry Program Committee,* Harold Eist, M.D., chairperson, continued its practice of current, practical, interactive sessions at its meeting in Los Angeles on Oct. 20–24, 1991. The institute's theme, "Overcoming Challenges With Diversity," was reflected in a vast range of topics, such as psychopharmacology, gang violence, managed care, sexual harassment, borderline disorders, and insomnia. Seventeen professional groups held meetings in conjunction with the institute, including the Pacific Rim College of Psychiatrists, which held a 3-day meeting before the institute. Dr. Eist chaired "The Experience of a Heart Attack: Medical and Psychiatric Perspectives," for which a faculty of a cardiologist and psychiatrists came together to discuss these issues around a "love-your-heart" luncheon. David O. Olenik, M.D., is chairperson of the program committee for the 1992 H&CP institute, which will be held in Toronto on Oct. 23–27.

The *Task Force on the Homeless Mentally Ill,* Frederic I. Kass, M.D., chairperson, published its second interim report, "Homeless Families and Children: A Psychiatric Perspective." This report and the 1990 report "General Directions for Public Policy in Behalf of the Mentally Ill Among the Homeless Population" are available on request from the APA Office of Psychiatric Services. The task force completed a book that includes recommendations and a summary of developments in psychiatric services for the homeless mentally ill in the last several years. The task force has initiated workshops for district branches at the last two APA annual meetings, with the goal of facilitating exchange of information, know-how, and enthusiasm among district branches interested in developing local programs for the homeless mentally ill population.

The *Task Force on Family/Systems Therapy,* Fred Gottlieb, M.D., chairperson, created linkages to other APA components, raising consciousness about family/systems therapy in terms of considerations for treatment, reimbursement, and education. The task force has reviewed previously published APA documents on the topic and has developed a framework for approaching current issues that encompass definitions, considerations for treatment, education, practices (including the possibility of practice guidelines), third-party payment issues (including coding and reimbursement), and research.

The *Task Force on Clinician Safety,* William Dubin, M.D., chairperson, refined its report. It is anticipated that the report will be recommended for publication in 1992. The task force continued its study of the issues, including facilitation of a milieu that would minimize violence, threats, and assaults in forensic hospitals and involvement of legal authorities in threats.

The *Committee on Liaison With the American Hospital Association,* Stuart Keill, M.D., chairperson, in concert with its counterpart committee at the American Hospital Association, recommended that the joint committee of the two associations be disbanded. To ensure ongoing liaison and communication, and on the recommendation of the council, the boards of both APA and the American Hospital Association agreed that a representative and staff person of the American Hospital Association would serve as consultants to several APA councils and that an APA representative and staff person would participate in the American Hospital Association's Governing Council on Psychiatric and Substance Abuse Services. Both organizations encourage appointment of members representing the interests of psychiatry and hospitals on key policy development committees critical to concerns of both organizations. Throughout the 30 years of its existence, the joint committee promoted cooperation between the two organizations on programs, positions, and legislative and regulatory matters.

It has been a busy and rewarding year. The council anticipates several challenges in the coming year relating to access to services, quality of care, and the strength of psychiatry's contribution in the many areas that touch on treatment and services.

# The Council on Psychiatry and Law

## Paul Appelbaum, M.D., Chairperson

In December of 1989, the APA Board of Trustees approved a resource document proposed by the council concerning patients' right to refuse medication. The document was approved with the proviso that the council would review the experiences of states that had mandated judicial review for refusals of medication in order to understand the problems and any possible benefits. After studying a survey of the states that require judicial review of involuntary treatment decisions, the council agreed to prepare a supplement to the resource document on the right to refuse medication that would focus on the disadvantages and advantages of judicial review systems. The supplemental paper, which also includes model guidelines for improving the efficiency of the judicial model, has been completed, was approved by the Joint Reference Committee in October 1991, and will be forwarded to the Assembly of District Branches in November.

The council has continued examining psychiatrists' responsibility for reporting impaired driving by mentally ill persons to departments of motor vehicles. Council member Jeffrey Metzner, M.D., chaired a task force of the Federal Highway Administration that examined commercial driving permits for people suffering psychiatric diseases or disorders. Dr. Metzner shared the final report of the task force with council members at the council's fall meeting. A representative of the Council on Aging joined the council during the fall meeting for its discussion. The Council on Psychiatry and Law and the Council on Aging will appoint a working group to explore this issue further, specifically to determine what psychiatrists know about the impacts of various disorders and medications on driving capacity and what sorts of responsibilities psychiatrists should have. The initial focus of the subcommittee will be the effect of dementia on the driving capacity of older persons.

The council met with the chairperson of the Committee on Women to discuss laws designed to control patient-therapist sexual contact. States have adopted a variety of statutory approaches to the problem of sexual relationships between patients and therapists. Basically, the three approaches states are taking in legislation are l) statutes to make civil suits easier, e.g., by increasing statutes of limitations or shielding complainants from questions about prior sexual activity, 2) statutes criminalizing sexual misconduct by physicians, and 3) statutes regulating the reporting of sexual misconduct by physicians. At its October meeting, the Joint Reference Committee instructed the council to develop, in conjunction with the Committee on Women, model legislation for use by the district branches. A working group has been established for this purpose and will report to the council in May.

The council, in conjunction with the Commission on Judicial Action, has been exploring peer review of expert testimony. As a result of this exploration, the council believes that peer review may be a useful mechanism for improving the quality of psychiatrists' performance in court. Further, the council believes that as experience with and knowledge about peer review grows, it is likely that models serving the ultimate end of increasing the quality of expert testimony will develop. The council has drafted a proposed position statement on peer review of expert testimony and a proposed resource document on peer review of psychiatric expert testimony, which may assist groups that are interested in developing peer review mechanisms. Both of these documents were approved by the Joint Reference Committee and will be referred to the Assembly of District Branches (the position statement for approval, the resource document for review) at its November meeting. The council hopes both documents will be approved by the Board of Trustees at its December meeting. Additionally, the council feels that a task force on peer review of psychiatric expert testimony should be established to further study this issue and to develop mechanisms for implementation of peer review programs. The American Academy of Psychiatry and Law has agreed to collaborate in the work of this task force. The Joint Reference Committee has recommended that the Board of Trustees approve the establishment of this task force.

The council also has been working with the Joint Commission on Government Relations and the Division of Government Relations in dealing with such issues as guardianship and advance directives for psychiatric treatment.

The *Committee on Confidentiality,* Renee L. Binder, M.D., chairperson, has established a column in *Psychiatric News* that addresses current confidentiality topics in a question-and-answer format. The committee is currently exploring the development of a new confidentiality videotape, the issue of confidentiality and technology, and confidentiality issues raised by managed care.

The *Task Force on Disclosure of Psychiatric Treatment Records in Child Custody Disputes,* Carl Malmquist, M.D., chairperson, has completed its charge. The task force report, "Disclosure of Psychiatric Treatment Records in Child Custody Disputes," has been approved by the Board of Trustees, and publication is expected in mid to late November. This report points out that judicial decisions concerning disclosure in custody proceedings of information obtained during psychiatric treatment often neglect harms that may result from such disclosure. The report recommends directing courts to order that information revealed in psychiatric treatment be disclosed in custody proceedings only when one disputant offers substantive evidence that the parent who has received psychiatric treatment is currently unable to provide adequate care for the child and when the information sought is likely to support this allegation.

The *Task Force on Use and Misuse of Psychiatric Diagnoses in the Courts,* Seymour Halleck, M.D., chairperson, has completed its report. The Joint Reference Committee has approved the draft and referred the report to the Board of Trustees for approval. The document will be reviewed by the Assembly of District Branches at its November meeting. The legal system has increasingly called on psychiatrists to help resolve legal conflicts, and the report aims to clarify legitimate uses of diagnoses in legal adjudication and their limitations. Additionally, the council has been working closely with the Task Force on DSM-IV to address the ways in which the complicated questions involved in legal uses of *DSM-IV* could be addressed.

The *Task Force on Consent to Voluntary Hospitalization,* Francine Cournos, M.D., chairperson, hopes to have a final draft of its report for review by the council at its May meeting. This report will focus on the issues involved in *Zinermon v. Burch.* This case raised questions about the legitimacy of consent given by patients who may be incompetent at the time of voluntary hospitalization and suggested that those patients should be dealt with by involuntary commitment.

# The Council on Research

Herbert Pardes, M.D., Chairperson

The Council on Research, in conjunction with its components, is the body within the Association that ensures the vigor of the psychiatric research enterprise by focusing on science policy and scientific assessment issues, research studies, and, especially important, research training issues. The council has been carefully monitoring science policy issues, particularly those concerned with animal research, research appropriations,conflict of interest issues, training and infrastructure needs, and child psychiatry research funding. Many of these issues and those of the research components are addressed in the column "News From the Council on Research" in *Psychiatric Research Report (PRR),* the Office of Research quarterly newsletter. Individuals who would like to receive *PRR* should contact the APA Office of Research.

The council was delighted to meet and continue its annual discussions with key leaders of the federal research agencies, including the Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA), the National Institute of Mental Health (NIMH), the National Institute on Alcohol Abuse and Alcoholism (NIAAA), and the National Institute on Drug Abuse (NIDA). Over the years these meetings have provided an opportunity for informal collaboration and have identified issues of mutual concern. This year's discussions focused largely on the reorganization of ADAMHA. Under the proposed reorganization (which had not received legislative approval at the time of this writing), the research programs of NIMH, NIDA, and NIAAA would be administratively housed within the National Institutes of Health (NIH). Service and prevention programs would remain with ADAMHA, which would be renamed the Alcohol, Drug Abuse, and Mental Health Services Administration (ADAMHSA). The council voiced concern about the reorganization's potential effect on the successful coalition of groups supporting the three institutes. Other topics addressed with the agencies included the psychiatric research infrastructure, research competitiveness in departments of psychiatry, and research appropriations.

The council collaborated with the APA Division of Government Relations and the Joint Commission on Government Relations on a number of important issues. The council was particularly concerned with legislation that would cap indirect costs at 26% for ADAMHA and NIH federal grants. In addition, the council is asking that APA formally advocate a loan forgiveness program for psychiatric research trainees and that the Division of Government Relations assist with the implementation of this policy.

The council administers two APA awards—the Lilly Psychiatric Research Fellowship and the Kempf Fund Award for Research Development in Psychobiological Psychiatry. The council appointed Ronald Rieder, M.D., Judith Rapoport, M.D., Robert Hirschfeld, M.D., and Walter Hong, M.D., to review the 1992 applications and select the winners. The winners of the 1991 Kempf award were David L. Braff, M.D. (senior awardee) and Neal R. Swerdlow, M.D. (junior awardee). Robert T. Malison, M.D., received the Lilly Psychiatric Research Fellowship.

Following are details of the activities of components under the Council on Research.

The final report of the *Task Force on Tardive Dyskinesia,* John Kane, M.D., chairperson, was approved by the Board of Trustees in December 1990 and is to be published in December 1991 (1). The final report of the *Task Force on Quantitative Electrophysiological Assessment,* Robert Freedman, M.D., chairperson, was also approved by the Board of Trustees in December 1990 and was published in July 1991 (2). The council thanked both task forces for their important contributions to the literature and recommended to the Board that they be disbanded.

The *Committee on Research on Psychiatric Treatments,* John Kane, M.D., chairperson, continues to assess and respond to scientific issues regarding psychiatric treatment (for example, a possible relationship between antidepressants and suicide). In conjunction with the Council on Addiction Psychiatry, the committee has recommended the establishment of a task force on nicotine dependence to address this important public health issue. If approved by the Board of Trustees, the task force would be charged with educating psychiatrists regarding the seriousness of nicotine addiction and the need for treatment, assessing current scientific information in the field, identifying reimbursement issues, developing recommendations for training, establishing a general research agenda, and developing a position paper.

The committee has also met with a representative of the U.S. Food and Drug Administration (FDA) and with a representative of NIMH regarding the development of a treatment research branch of NIMH. It continues to review APA's efforts to develop practice guidelines and to monitor issues involving clozapine and anticonvulsant drugs.

Further, the Committee on Research on Psychiatric Treatments oversees treatment-related task forces, including the Task Force on Electroconvulsive Therapy and the Task Force on Psychosocial Treatment Research. Summaries of their activities follow.

The *Task Force on Electroconvulsive Therapy,* Richard Weiner, M.D., Ph.D., chairperson, continues to monitor proposed regulations published by the FDA to reclassify ECT devices from class III (requiring premarket approval) to class II (requiring a performance standard) for use in treating severe depression. The task force, working in conjunction with the Division of Government Relations and coordinating its activities with those of other groups and individual psychiatrists, hopes to modify the regulations to include mania and schizophrenia in this reclassification and to clarify the meaning of "severe depression."

The *Task Force on Psychosocial Treatment Research,* John Docherty, M.D., chairperson, submitted a draft of its final report. The document was approved by the Committee on Research on Psychiatric Treatments in May 1991 and by the Council on Research in September 1991. It was forwarded to the Joint Reference Committee, and that body returned it to the council for modification.

The *Steering Committee on Practice Guidelines,* John S. McIntyre, M.D., chairperson, has been establishing the process for developing practice guidelines for psychiatrists. It has outlined a standardized method to ensure that the final products are based on well-documented evidence, have substantial clinician input, and are widely reviewed. A variety of dissemination strategies are under consideration. Guidelines in four areas have been drafted by distinct work groups, with input from a wide range of individuals, and are presently in varying stages of completeness. The four areas are eating disorders, major depression, adult outpatient evaluation, and adult inpatient evaluation. Future guideline topics under consideration include schizophrenia, evaluation and management of mental disorders in the geriatric population, and bipolar disorder. Steering committee members and staff continue active liaison with organizations and agencies involved in various aspects of practice guidelines development. In addition, a program for achieving more sophisticated approaches to developing practice guidelines was recently funded by NIMH.

The *Committee on Research Training,* Ron Rieder, M.D., chairperson, continues to focus on the recruitment and development of psychiatric researchers. The committee is attempting to generate support for research by medical students during the summer in departments of psychiatry and is developing a report on women in research. Mentorship is another focus; the committee has proposed a workshop on research mentoring for the 1992 annual meeting, after the success of the 1991 workshop on overcoming obstacles to starting research. In September 1991 the committee developed the "Guide for Residents and Fellows Seeking Research Training Opportunities," which is designed to help trainees ask questions about and evaluate the available opportunities for research in various departments of psychiatry. This guide has been distributed through the Psychiatric Research Training Clearinghouse. The committee has suggested that the guide also be included in a second edition of the "Directory of Research Fellowship Opportunities in Psychiatry," the first edition of which was published by the Office of Research in October 1990. This resource includes listings of research fellowship opportunities compiled from responses to a questionnaire about postgraduate research training opportunities that was sent to directors of residency training in November 1989. It also includes introductory material about APA programs and activities, information on research careers, and listings of programs and suggestions on how readers might use them.

The Residency Review Committee for Psychiatry of the Accreditation Council for Graduate Medical Education is developing research requirements for geriatric fellowship programs (the first such research training requirements in a subspecialty). The committee and council are strongly supporting the requirement of a research component in fellowship training. The committee also asked APA to formally request the Residency Review Committee to require that residency training programs have a plan for conducting research that can be offered to residents interested in research. This recommendation was approved by the Joint Reference Committee in September 1991 and referred to the Board of Trustees for consideration in December.

The *Committee on the Biographical Directory and Research on Psychiatric Professional Activities,* Robert Dorwart, M.D., chairperson, is exploring a number of publication options for future directories and will present several to the council for its consideration next spring. Specifically, the committee believes that a smaller, less costly, more timely directory may be needed. Most research data would then be collected through smaller, specifically targeted sample surveys separate from the directory process. The committee is working with the Offices of Research and Membership, the Council on Research, and the Committee on Membership to further develop these plans.

The committee continues to analyze the data collected from the Professional Activities Survey and has provided data to the Committee on the Chronically Mentally Ill and to the Task Force on Psychiatrist Payment for the study of specific topics. The committee is also writing an article describing basic survey findings for publication in an APA journal, and it is working collaboratively with researchers at Harvard University, Johns Hopkins University, and the University of Arkansas to rapidly analyze and disseminate survey findings on policy issues that are important to APA and the field.

The *Committee on Psychiatric Diagnosis and Assessment,* Layton McCurdy, M.D., chairperson, oversees diagnostic assessment activities, including the work of the Task Force on DSM-IV (separate report follows). In addition to overseeing this important component, the committee has considered the linkages between *DSM-IV* and *ICD-10,* the implications of the profusion of suggestions for new *DSM* diagnoses, and coordination between *DSM* efforts and education and forensic issues. The committee has also been seeking to further communication between psychiatrists interested in neurophysiological assessment techniques and the American Board of Psychiatry and Neurology, which recently developed a program for added qualification for psychiatrists and neurologists in this area.

The *Task Force on DSM-IV,* Allen Frances, M.D., chairperson, has completed work on the *DSM-IV Options Book* (3), a comprehensive listing of issues identified in the process of developing *DSM-IV* and options for their resolution. Data collection has continued over the last year through NIMH-focused field trials. Results from the field trials, as well as data reanalysis funded by the John D. and Catherine T. McArthur Foundation, will be available by May 1992 and will help the task force make final decisions about specific diagnostic categories in *DSM-IV.* The task force is also supervising the efforts of the DSM-IV Primary Care Work Group, which has begun some preliminary work on a primary care version of *DSM-IV.* The task force edits bimonthly columns on *DSM-IV* in *Hospital & Community Psychiatry* and produces *DSM-IV Update,* a semiannual newsletter. Individuals wishing to receive copies of *DSM-IV Update* should write to the APA Office of Research.

The *Task Force on Traumatic Brain Injury,* Stuart Yudofsky, M.D., chairperson, was established in 1990 and reports directly to the Council on Research. It is focusing its efforts on the education of physicians through the development of a model curriculum for medical students and residents, liaison with other medical societies (i.e., pediatricians, family practitioners, and internists), and presentations on the psychiatric aspects of traumatic brain injury to other medical societies. The task force also plans to develop an informational brochure for victims of traumatic brain injury and their families. The task force presented a very successful workshop at the 1991 annual meeting and hopes to organize a symposium for the 1992 annual meeting in Washington, D.C.

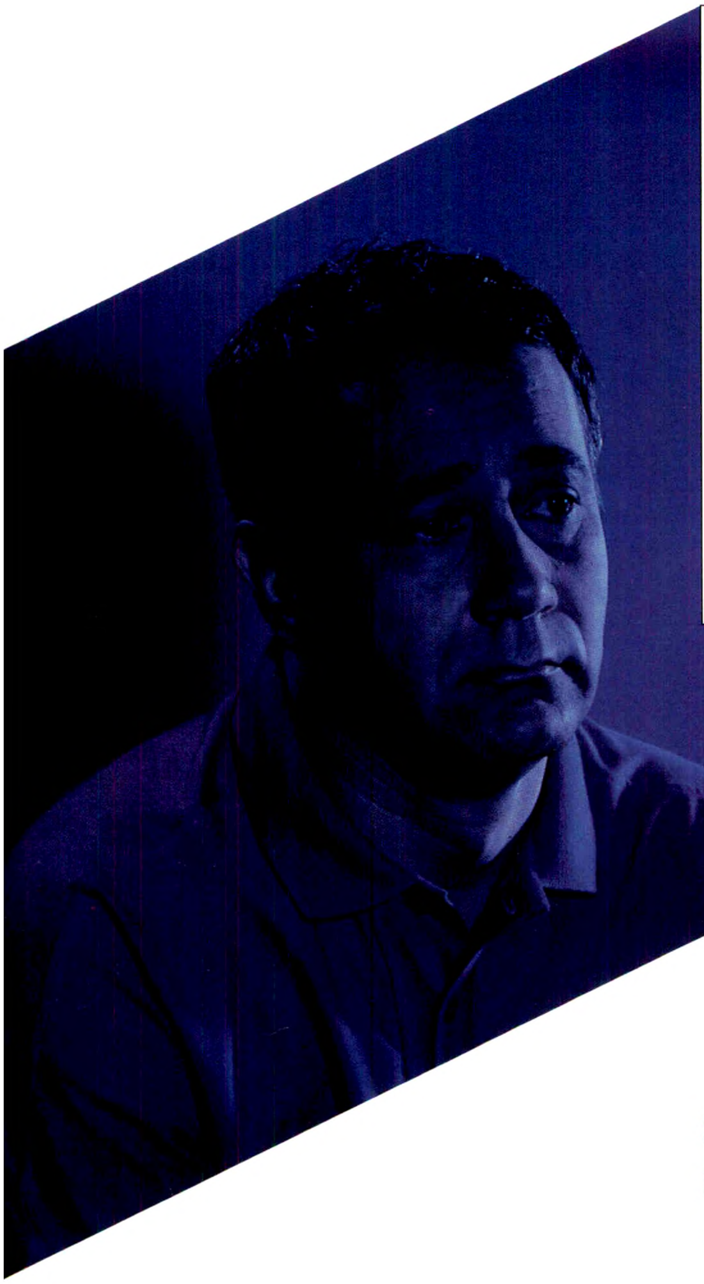
**WELLBUTRIN®**
**(bupropion HCl),**
**the non-serotonergic[1-4]**
**alternative to**
**Prozac®***
**(fluoxetine HCl)**
**for many**
**patients...**

---

* Prozac® is a registered trademark of Dista Products Co., a division of Eli Lilly and Company.

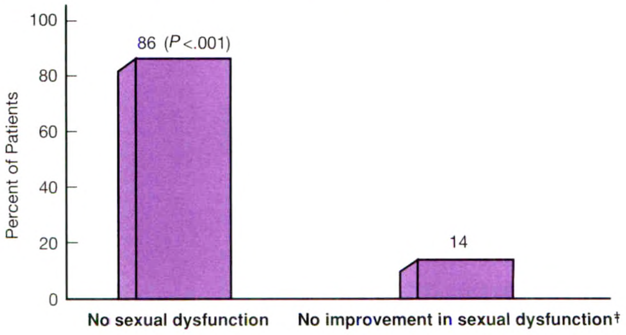
# Bill's doctor wants a new-generation antidepressant that minimizes risk of sexual dysfunction but is non-serotonergic.

■ Because WELLBUTRIN may cause little sexual dysfunction, it may improve patient compliance.[5]



**Relieves depression with fewer adverse effects on sexual performance**

Male Patients Switched to WELLBUTRIN Who During Previous Antidepressant Therapy* Experienced Sexual Dysfunction (N=28)[5]†



*Including tricyclics, MAO inhibitors, maprotiline, and trazodone.

**Start with non-serotonergic**

# Wellbutrin®

(BUPROPION HCl)

**Relieves depression with few life-style disruptions**

†Impairments that ceased to occur after treatment with WELLBUTRIN were decreased libido, decreased erectile capacity, or delayed or retrograde ejaculation.

‡Of the four patients (age range: 50 to 67) who demonstrated no change in sexual dysfunction, two were diabetic and two had lifelong histories of sexual disability.

# The man whose medication caused sexual dysfunction

Name: Bill – Occupation: Unemployed administrative assistant
Age: 48 – Height: 5'10" – Weight: 170 lb

**History**
Patient complains of fatigue, inability to concentrate, and feelings of worthlessness since staff cuts at the corporation where he worked for 21 years resulted in the loss of his job. He has failed to begin company-sponsored job retraining program and to look for a new job.

**Diagnosis: Depression**

**Initial treatment**
After 2 months of antidepressant treatment, patient complains of sexual dysfunction (erectile failure and decreased libido), which had not been a problem prior to antidepressant treatment. Although patient's depression has improved, he insists the medication is causing the sexual dysfunction and requests that medication be discontinued.

**Recommendation**
Discontinue current antidepressant and switch to a new-generation, non-serotonergic antidepressant. Start WELLBUTRIN to relieve depression and minimize risk of sexual dysfunction.

**Outcome**
After 4 weeks of therapy with WELLBUTRIN, patient reports feeling more energetic.
Sexual performance is normal.
He has enrolled in job retraining program.

*See brief summary of full prescribing information on last page of this advertisement.*

# Start with WELLBUTRIN, the non-serotonergic alternative to Prozac®* (fluoxetine HCl) for many patients.

## As a new-generation antidepressant, WELLBUTRIN offers:

- Effective relief of depression with few life-style disruptions
- Few cardiovascular effects[6-8]
- Few anticholinergic effects[3,9]
- Little or no weight gain[3,10]
- Little or no daytime drowsiness[9]
- Minimal risk of sexual dysfunction[5]

The principal medically important adverse reaction with WELLBUTRIN is seizure, which occurs in approximately four-tenths of one percent of patients. This incidence may exceed that of other marketed antidepressants, although no direct comparative studies have been conducted. For more information about dosing to achieve optimal patient response and recommendations for reducing the risk of side effects, see full prescribing information, especially the DOSAGE AND ADMINISTRATION and WARNINGS sections.

# WELLBUTRIN® (BUPROPION HYDROCHLORIDE) Tablets

**Before prescribing, please consult complete product information, a summary of which follows:**
**INDICATIONS AND USAGE:** Wellbutrin is indicated for the treatment of depression. A physician considering the initiation of Wellbutrin should be aware that the drug may cause generalized seizures with an approximate incidence of 0.4% (4/1000). This incidence may exceed that of other antidepressants as much as fourfold. This relative risk is only an approximation since no direct comparative studies have been conducted.
**CONTRAINDICATIONS:** Wellbutrin is contraindicated in patients: with a seizure disorder; with a current or prior diagnosis of bulimia or anorexia nervosa, because of a higher incidence of seizures noted in such patients; who have shown an allergic response to it; or who are currently being treated with an MAO inhibitor. At least 14 days should elapse between discontinuation of an MAO inhibitor and initiation of treatment with Wellbutrin
**WARNINGS: SEIZURES: Wellbutrin is associated with seizures in approximately 0.4% (4/1000) of patients treated at doses up to 450 mg/day. This incidence of seizures may exceed that of other marketed antidepressants by as much as fourfold. This relative risk is only an approximate estimate because no direct comparative studies have been conducted. The estimated seizure incidence for Wellbutrin increases almost tenfold between 450 and 600 mg/day, which is twice the usually required daily dose (300 mg) and one and one-third the maximum recommended daily dose (450 mg). Given the wide variability among individuals and their capacity to metabolize and eliminate drugs, this disproportionate increase in seizure incidence with dose incrementation calls for caution in dosing.**
**During the initial development, 25 among approximately 2400 patients treated with Wellbutrin experienced seizures. At the time of seizure, 7 patients were receiving daily doses of 450 mg or below, for an incidence of 0.33% (3/1000) within the recommended dose range. Twelve (12) patients experienced seizures at 600 mg per day (2.3% incidence); 6 additional patients had seizures at daily doses between 600 and 900 mg (2.8% incidence).**
**A separate, prospective study was conducted to determine the incidence of seizure during an 8 week treatment exposure in approximately 3200 additional patients who received daily doses of up to 450 mg. Patients were permitted to continue treatment beyond 8 weeks if clinically indicated. Eight (8) seizures occurred during the initial 8 week treatment period and 5 seizures were reported in patients continuing treatment beyond 8 weeks, resulting in a total seizure incidence of 0.4%.**
**The risk of seizure appears to be strongly associated with dose and the presence of predisposing factors. A significant predisposing factor (e.g., history of head trauma or prior seizure, CNS tumor, concomitant medications that lower seizure threshold, etc.) was present in approximately one-half of the patients experiencing a seizure. Sudden and large increments in dose may contribute to increased risk. While many seizures occurred early in the course of treatment, some seizures did occur after several weeks at fixed dose.**
***Recommendations for reducing the risk of seizure:* Retrospective analysis of clinical experience gained during the development of Wellbutrin suggests that the risk of seizure may be minimized if (1) the total daily dose of Wellbutrin does *not* exceed 450 mg, (2) the daily dose is administered t.i.d., with each single dose not to exceed 150 mg to avoid high peak concentrations of bupropion and/or its metabolites, and (3) the rate of incrementation of dose is very gradual. Extreme caution should be used when Wellbutrin is (1) administered to patients with a history of seizure, cranial trauma, or other predisposition(s) toward seizure, or (2) prescribed with other agents (e.g., antipsychotics, other antidepressants, etc.) or treatment regimens (e.g., abrupt discontinuation of a benzodiazepine) that lower seizure threshold.**
**Potential for Hepatotoxicity:** In rats receiving large doses of bupropion chronically, there was an increase in incidence of hepatic hyperplastic nodules and hepatocellular hypertrophy. In dogs receiving large doses of bupropion chronically, various histologic changes were seen in the liver, and laboratory tests suggesting mild hepatocellular injury were noted. Although scattered abnormalities in liver function tests were detected in patients participating in clinical trials, there is no clinical evidence that bupropion acts as a hepatotoxin in humans.
**PRECAUTIONS: General:**
***Agitation and Insomnia:*** A substantial proportion of patients treated with Wellbutrin experience some degree of increased restlessness, agitation, anxiety, and insomnia, especially shortly after initiation of treatment. In clinical studies, these symptoms were sometimes of sufficient magnitude to require treatment with sedative/hypnotic drugs. In approximately 2% of patients, symptoms were sufficiently severe to require discontinuation of Wellbutrin treatment.
***Psychosis, Confusion, and Other Neuropsychiatric Phenomena:*** Patients treated with Wellbutrin have been reported to show a variety of neuropsychiatric signs and symptoms including delusions, hallucinations, psychotic episodes, confusion, and paranoia. Because of the uncontrolled nature of many studies, it is impossible to provide a precise estimate of the extent of risk imposed by treatment with Wellbutrin. In several cases, neuropsychiatric phenomena abated upon dose reduction and/or withdrawal of treatment.
***Activation of Psychosis and/or Mania:*** Antidepressants can precipitate manic episodes in Bipolar Manic Depressive patients during the depressed phase of their illness and may activate latent psychosis in other susceptible patients. Wellbutrin is expected to pose similar risks.
***Altered Appetite and Weight:*** A weight loss of greater than 5 pounds occurred in 28% of Wellbutrin patients. This incidence is approximately double that seen in comparable patients treated with tricyclics or placebo. Furthermore, while 34.5% of patients receiving tricyclic antidepressants gained weight, only 9.4% of patients treated with Wellbutrin did. Consequently, if weight loss is a major presenting sign of a patient's depressive illness, the anorectic and/or weight reducing potential of Wellbutrin should be considered.
***Suicide:*** The possibility of a suicide attempt is inherent in depression and may persist until significant remission occurs. Accordingly, prescriptions for Wellbutrin should be written for the smallest number of tablets consistent with good patient management.
**Use in Patients with Systemic Illness:** There is no clinical experience establishing the safety of Wellbutrin in patients with a recent history of myocardial infarction or unstable heart disease. Therefore, care should be exercised if it is used in these groups.
Because bupropion HCl and its metabolites are almost completely excreted through the kidney and metabolites are likely to undergo conjugation in the liver prior to urinary excretion, treatment of patients with renal or hepatic impairment should be initiated at reduced dosage as bupropion and its metabolites may accumulate in such patients beyond concentrations expected in patients without renal or hepatic impairment. The patient should be closely monitored for possible toxic effects of elevated blood and tissue levels of drug and metabolites.
**Information for Patients:** Consult complete product information.
**Drug Interactions:** No systematic data have been collected on the consequences of the concomitant administration of Wellbutrin and other drugs.
However, animal data suggest that Wellbutrin may be an inducer of drug metabolizing enzymes. This may be of potential clinical importance because the blood levels of co-administered drugs may be altered.
Alternatively, because bupropion is extensively metabolized, the co-administration of other drugs may affect its clinical activity. In particular, care should be exercised when administering drugs known to affect hepatic drug metabolizing enzyme systems (e.g., carbamazepine, cimetidine, phenobarbital, phenytoin).
Studies in animals demonstrate that the acute toxicity of bupropion is enhanced by the MAO inhibitor phenelzine (see CONTRAINDICATIONS).
Limited clinical data suggest a higher incidence of adverse experiences in patients receiving concurrent administration of Wellbutrin and L-dopa. Administration of Wellbutrin to patients receiving L-dopa concurrently should be undertaken with caution, using small initial doses and small gradual dose increases.
Concurrent administration of Wellbutrin and agents which lower seizure threshold should be undertaken only with extreme caution (see WARNINGS). Low initial dosing and small gradual dose increases should be employed.
**Carcinogenesis, Mutagenesis, Impairment of Fertility:** Lifetime carcinogenicity studies were performed in rats and mice at doses up to 300 and 150 mg/kg/day, respectively. In the rat study there was an increase in nodular proliferative lesions of the liver at doses of 100 to 300 mg/kg/day; lower doses were not tested. The question of whether or not such lesions may be precursors of neoplasms of the liver is currently unresolved. Similar liver lesions were not seen in the mouse study, and no increase in malignant tumors of the liver and other organs was seen in either study.
Bupropion produced a borderline positive response (2-3 times control mutation rate) in some strains in the Ames bacterial mutagenicity test, and a high oral dose (300, but not 100 or 200 mg/kg) produced a low incidence of chromosomal aberrations in rats. The relevance of these results in estimating the risk of human exposure to therapeutic doses is unknown.
A fertility study was performed in rats; no evidence of impairment of fertility was encountered at oral doses up to 300 mg/kg/day.
**Pregnancy: *Teratogenic Effects:*** Pregnancy Category B: Reproduction studies have been performed in rabbits and rats at doses up to 15-45 times the human daily dose and have revealed no definitive evidence of impaired fertility or harm to the fetus due to bupropion. (In rabbits, a slightly increased incidence of fetal abnormalities was seen in two studies, but there was no increase in any specific abnormality). There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
**Labor and Delivery:** The effect of Wellbutrin on labor and delivery in humans is unknown.
**Nursing Mothers:** Because of the potential for serious adverse reactions in nursing infants from Wellbutrin, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

**Pediatric Use:** The safety and effectiveness of Wellbutrin in individuals [illegible] established.
**Use in the Elderly:** Wellbutrin has not been systematically evaluated [illegible]
**ADVERSE REACTIONS:** (See also WARNINGS and PRECAUTIONS [illegible] in patients treated with Wellbutrin are agitation, dry mouth, insomnia [illegible] constipation, and tremor.
Adverse events were sufficiently troublesome to cause discontinu[illegible] approximately ten percent of the 2400 patients and volunteers who [illegible] product's initial development. The more common events causing disco[illegible] disturbances (3.0%), primarily agitation and abnormalities in mental sta[illegible] (2.1%), primarily nausea and vomiting; neurological disturbances (1.7[illegible] sleep disturbances; and dermatologic problems (1.4%), primarily ra[illegible] that many of these events occurred at doses that exceed the recom[illegible]
The table below is presented solely to indicate the relative frequ[illegible] representative controlled clinical studies conducted to evaluate t[illegible] under relatively similar conditions of daily dosage (300-600 mg), setting [illegible] cited cannot be used to predict precisely the incidence of untoward [illegible] practice where patient characteristics and other factors must diffe[illegible] clinical trials. These incidence figures also cannot be compared with the [illegible] involving related drug products as each group of drug trials is conducted [illegible] Finally, it is important to emphasize that the tabulation does not ref[illegible] importance of the events. A better perspective on the serious adverse events [illegible] is provided in the WARNINGS and PRECAUTIONS sections.

**TREATMENT EMERGENT ADVERSE EXPERIENCE INCIDENCE IN PLACEBO-CO[illegible]**
**(Percent of Patients Reporting)**

| Adverse Experience | Wellbutrin Patients (n = 323) | Placebo Patients (n = 185) |
|---|---|---|
| CARDIOVASCULAR | | |
| Cardiac Arrhythmias | 5.3 | 4.3 |
| Dizziness | 22.3 | 16.2 |
| Hypertension | 4.3 | 1.6 |
| Hypotension | 2.5 | 2.2 |
| Palpitations | 3.7 | 2.2 |
| Syncope | 1.2 | 0.5 |
| Tachycardia | 10.8 | 8.6 |
| DERMATOLOGIC | | |
| Pruritus | 2.2 | 0.0 |
| Rash | 8.0 | 6.5 |
| GASTROINTESTINAL | | |
| Anorexia | 18.3 | 18.4 |
| Appetite Increase | 3.7 | 2.2 |
| Constipation | 26.0 | 17.3 |
| Diarrhea | 6.8 | 8.6 |
| Dyspepsia | 3.1 | 2.2 |
| Nausea/Vomiting | 22.9 | 18.9 |
| Weight Gain | 13.6 | 22.7 |
| Weight Loss | 23.2 | 23.2 |
| GENITOURINARY | | |
| Impotence | 3.4 | 3.1 |
| Menstrual Complaints | 4.7 | [illegible] |
| Urinary Frequency | 2.5 | 2.2 |
| Urinary Retention | 1.9 | 2.2 |
| MUSCULOSKELETAL | | |
| Arthritis | 3.1 | 2.7 |
| NEUROLOGICAL | | |
| Akathisia | 1.5 | 1.1 |
| Akinesia/Bradykinesia | 8.0 | 8.6 |
| Cutaneous Temperature Disturbance | 1.9 | 1.6 |

| Adverse Experience | [illegible] | [illegible] |
|---|---|---|
| Dry Mouth | [illegible] | [illegible] |
| Excessive Sweating | [illegible] | [illegible] |
| Headache/Migraine | [illegible] | [illegible] |
| Impaired Sleep Quality | [illegible] | [illegible] |
| Increased Salivary Flow | [illegible] | [illegible] |
| Insomnia | [illegible] | [illegible] |
| Muscle Spasms | [illegible] | [illegible] |
| Pseudoparkinsonism | [illegible] | [illegible] |
| Sedation | [illegible] | [illegible] |
| Sensory Disturbance | [illegible] | [illegible] |
| Tremor | [illegible] | [illegible] |
| NEUROPSYCHIATRIC | | |
| Agitation | [illegible] | [illegible] |
| Anxiety | [illegible] | [illegible] |
| Confusion | [illegible] | [illegible] |
| Decreased Libido | [illegible] | [illegible] |
| Delusions | [illegible] | [illegible] |
| Disturbed Concentration | [illegible] | [illegible] |
| Euphoria | [illegible] | [illegible] |
| Hostility | [illegible] | [illegible] |
| NONSPECIFIC | | |
| Fatigue | [illegible] | [illegible] |
| Fever/Chills | [illegible] | [illegible] |
| RESPIRATORY | | |
| Upper Respiratory Complaints | [illegible] | [illegible] |
| SPECIAL SENSES | | |
| Auditory Disturbance | [illegible] | [illegible] |
| Blurred Vision | [illegible] | [illegible] |
| Gustatory Disturbance | [illegible] | [illegible] |

*Events reported by at least 1% of Wellbutrin patients are included.

**Other Events Observed During the Development of Wellbutrin:** [illegible] exposure to Wellbutrin varied greatly and a substantial proportion of the experien[illegible] uncontrolled clinical settings. During this experience, numerous adverse e[illegible] without appropriate controls, it is impossible to determine with certainty which eve[illegible] by Wellbutrin. The following enumeration is organized by organ system and desc[illegible] relative frequency of reporting in the data base. Events of major clinical import[illegible] the WARNINGS and PRECAUTIONS sections of the labeling.
The following definitions of frequency are used: Frequent adverse events are [illegible] at least 1/100 patients. Infrequent adverse events are those occurring in 1/100 t[illegible] events are those occurring in less than 1/1000 patients.
***Cardiovascular:*** Frequent was edema; infrequent were chest pain, EKG abnor[illegible] and nonspecific ST-T changes), and shortness of breath/dyspnea; rare were [illegible] myocardial infarction.
***Dermatologic:*** Frequent were nonspecific rashes; infrequent were alopecia [illegible] change in hair color, hirsutism and acne.
***Endocrine:*** Infrequent was gynecomastia; rare were glycosuria and hormo[illegible]
***Gastrointestinal:*** Infrequent were dysphagia, thirst disturbance, and liver damage [illegible] complaints, colitis, G.I. bleeding, intestinal perforation and stomach ulcer
***Genitourinary:*** Frequent was nocturia; infrequent were vaginal irritation, testicu[illegible] infection, painful erection, and retarded ejaculation; rare were dysuria, enuresis, urinary [illegible] ovarian disorder, pelvic infection, cystitis, dyspareunia, and painful ejaculation
***Hematologic/Oncologic:*** Rare were lymphadenopathy, anemia and pancytopen[illegible]
***Musculoskeletal:*** Rare was musculoskeletal chest pain
***Neurological:*** (see WARNINGS) Frequent were ataxia/incoordination, seizure, my[illegible] dystonia; infrequent were mydriasis, vertigo, and dysarthria; rare were EEG [illegible] neurological exam, impaired attention, sciatica and aphasia.
***Neuropsychiatric:*** (see PRECAUTIONS) Frequent were mania/hypomania, increase[illegible] decrease in sexual function, and depression; infrequent were memory impairment, deperso[illegible] dysphoria, mood instability, paranoia, formal thought disorder, and frigidity; rare [illegible]
***Oral Complaints:*** Frequent was stomatitis; infrequent were toothache, bruxism, gum [illegible] rare was glossitis.
***Respiratory:*** Infrequent were bronchitis and shortness of breath/dyspnea; rare were [illegible] disorder, pneumonia and pulmonary embolism.
***Special Senses:*** Infrequent was visual disturbance; rare was diplopia.
***Nonspecific:*** Frequent were flu-like symptoms; infrequent was nonspecific pain; rare were [illegible] related pain, infection, medication reaction and overdose.
**Observed During Clinical Practice:** Based on clinical practice experience in patien[illegible] spontaneously reported adverse reactions are uncommon. Data are insufficient to [illegible] their incidence or to establish causation. Voluntary reports of adverse reactions [illegible] since market introduction include:
***Cardiovascular:*** orthostatic hypotension
***Gastrointestinal:*** esophagitis, hepatitis
***Hemic and Lymphatic:*** ecchymosis, leukocytosis, leukopenia
***Musculoskeletal:*** arthralgia, myalgia, muscle rigidity/fever/rhabdomyolysis
***Nervous:*** coma, delirium, dream abnormalities, paresthesia, unmasking of tardive [illegible]
***Skin and Appendages:*** angioedema, exfoliative dermatitis, urticaria
***Special Senses:*** tinnitus

THE AMERICAN JOURNAL OF PSYCHIATRY

# Information for Authors

## GENERAL POLICIES

The requirements stated below are in accordance with the International Committee of Medical Journal Editors. See Uniform Requirements for Manuscripts Submitted to Biomedical Journals, N Engl J Med 1991; 324:424–428.

### Prior Publication

Manuscripts are accepted for consideration by the *American Journal of Psychiatry* with the understanding that they represent original material, have not been published previously, are not being considered for publication elsewhere, and have been approved by each author. Any form of publication other than an abstract of no more than 400 words constitutes prior publication. This includes components of symposia, proceedings, transactions, books (or chapters), invited articles, or reports of any kind, regardless of differences in readership, as well as electronic data bases of public nature. Authors submitting manuscripts containing data or clinical observations already used in published papers or used in papers that are in press, submitted for publication, or to be submitted shortly should provide this information and copies of those papers to the Editor. An explanation of the differences between the papers should be included.

### Copyright Transfer and Submission Approval

The *Journal* requires approval of manuscript submission by all authors in addition to transfer of copyright to the American Psychiatric Association so that the author(s) and the Association are protected from misuse of copyrighted material. A submission approval and copyright transfer form will be forwarded to authors along with a letter acknowledging receipt of their manuscript. Manuscripts will not receive a final decision until a completed form has been received in the editorial office.

In addition, authors must obtain letters of permission from publishers for use of extensive quotations (more than 500 words). The *Journal* does not publish tables or figures that have been previously published or submitted elsewhere.

### Disclosure of Commercial Interests

All forms of support, including drug company support, must be acknowledged in the author's footnote (see "Acknowledgments" under the Title Page section). Also, authors must disclose in their cover letter any commercial or financial involvements that might present an appearance of a conflict of interest in connection with the submitted article, including but not limited to institutional or corporate affiliations not already specified in the author's footnote, paid consultancies, stock ownership or other equity interests, and patent ownership. At the Editor's discretion, this information may be shared with reviewers. Such involvements will not be grounds for automatic rejection of the manuscript. Should the article be accepted for publication, the Editor and the authors will consult on whether, and to what extent, this information should be included in the published article.

### Patient Anonymity

Ethical and legal considerations require careful attention to the protection of a patient's anonymity in case reports and elsewhere. Identifying information such as names, initials, hospital numbers, and dates must be avoided. Also, authors should disguise identifying information when discussing patients' characteristics and personal history.

### Informed Consent

Manuscripts that report the results of experimental investigation with human subjects must include a statement that informed consent was obtained after the procedure(s) had been fully explained. In the case of children, authors are asked to include information about whether the child's assent was obtained.

### Review Process

All papers are reviewed to determine the originality, validity, and importance of content and conclusions. In addition to the regular review process, peer review for statistical content may be required for some manuscripts. This will be determined by the *Journal*'s Statistical Editors. Authors will be sent reviewer comments that are judged to be useful to them. All reviewers remain anonymous. Once the Editor has made a final decision on a paper, the authors of that paper will be informed.

## SUBMISSION OF MANUSCRIPTS

The original manuscript and four copies should be submitted to John C. Nemiah, M.D., Editor, *American Journal of Psychiatry,* 1400 K St., N.W., Washington, DC 20005. Telephone: (202) 682-6020. FAX: (202) 682-6016. All correspondence will be sent to the first-named author unless otherwise specified. Papers should be accompanied by a cover letter indicating that the paper is intended for publication and specifying for which section of the *Journal* it is being submitted (i.e., Special Article, Regular Article, or Clinical and Research Report); papers will be reviewed only after such a statement has been received from the author.

Authors will be notified of the receipt of their paper and the number assigned to it. **This number must be included in all further correspondence.** It is imperative that the corresponding author of submitted papers notify the *Journal* of changes of address. Because of escalating postage costs, no manuscripts submitted to the *Journal* will be returned to authors except upon special request. Authors must make this request in their original submission letter and include a self-addressed, postage-paid envelope.

### Single Case Reports

Single case reports except for detailed longitudinal studies should be submitted as Letters to the Editor. All single case reports will be peer reviewed. Reports of successfully treated patients must include data on the number of patients treated unsuccessfully by the same method, with an indication of the temporal order of the successes and failures.

### Annual Meeting Papers

Papers may be submitted before the annual meeting, but they cannot be published until after the meeting. They must be accompanied by a statement that they are in final form. These papers receive the same peer review as other papers and must meet the requirements for one of the types of articles specified in the next section. The *Journal* no longer maintains right of first refusal for annual meeting papers.

## TYPES OF ARTICLES

### Special Articles

These are usually overview articles that bring together important information on a topic of general interest to psychiatry. Authors who have ideas for such articles are advised to check with the Editorial Office to ensure that a similar work has not already been submitted. Special Articles may not exceed 7,500 words, **including** an abstract of no more than 250 words, references, tables, and figures (to determine word equivalence, see section on Tables and Figures). This section is not intended to be a forum for the presentation of new data.

### Regular Articles

Regular Articles are original communications of scientific excellence in psychiatric medicine and advances in clinical research, containing new data derived from a sizable series of patients. Regular Articles contain no more than 3,800 words, **including** an abstract of no more than 250 words, references, tables, and figures (to determine word equivalence, see section on Tables and Figures).

### Clinical and Research Reports

Clinical and Research Reports present 1) data from pilot or uncontrolled studies with suggestive findings warranting further, more definitive investigation, 2) worthwhile replication studies, and 3) clinical studies involving a small number of patients. Essays, program descriptions, literature reviews, and single case reports do not meet the criteria for this section. These articles contain no more than 1,300 words, **including** an abstract of no more than 60 words, references, tables, and figures (to determine word equivalence, see section on Tables and Figures).

### Other Sections

**Letters to the Editor.** Brief letters (maximum of 500 words, including references; no tables or figures) will be considered if they include the notation "for publication." Letters critical of an article published in the *Journal* will automatically be sent to the authors for reply. Such letters **must** include the title and author of the article and the month and year of publication; they will not be processed without this information. Because of space limitations not all letters can be printed. The *Journal* will notify authors about the disposition of their letters but does not return those that are not published. A letter must be signed by all of its authors. All letters will be edited; edited letters will not be sent to authors for approval. Three copies of a letter are required. Letters that do not meet these specifications will be returned for revision. Reprints are not available. **Single case reports except for detailed longitudinal studies should be submitted as Letters to the Editor. Case reports submitted as Letters to the Editor will be peer reviewed.**

**Book Forum.** Books for review may be sent to the Book Forum Editor, Nancy C. Andreasen, M.D., Ph.D., Director, Mental Health Clinical Research Center, University of Iowa Hospitals and Clinics, 200 Hawkins Dr., Iowa City, IA 52242. Book reviews are usually solicited by the Book Forum Editor. Authors interested in reviewing a particular book should communicate directly with Dr. Andreasen. Reprints of reviews are not available.

## TYPING AND ARRANGING THE PAPER

All parts of the manuscript or letter to the Editor, including case reports, quotations, references, and tables, must be **double-spaced** throughout. Manuscripts must be typed in upper- and lowercase on one side only of 8.5×11 inch **nonerasable** bond paper. All four margins must be 1.5 inches. The manuscript should be arranged in the following order, with each item beginning a new page: 1) title page, 2) abstract, 3) text, 4) references, and 5) tables and/or figures. All pages must be numbered. The original and four copies of a manuscript, including tables and figures, should be submitted.

## STYLE SPECIFICATIONS

### Title Page

**Title.** The title should be informative and as brief as possible. Two-part titles should be avoided.

**Byline.** Authors listed in the byline should be limited to principal researchers and/or writers; collaborators may be acknowledged in a footnote. Authors' first names are preferred to initials. Degrees should be included after each author's name. The *Journal* subscribes to the Uniform Requirements for Manuscripts Submitted to Biomedical Journals (N Engl J Med 1991; 324:424-428) for authorship summarized here:

### Authorship

All persons designated as authors should qualify for authorship. Each author should have participated sufficiently in the work to take public responsibility for the content.

Authorship credit should be based only on substantial contributions to (a) conception and design, or analysis and interpretation of data, and (b) drafting the article or revising it critically for important intellectual content and on (c) final approval of the version to be published. Conditions (a), (b), and (c) must all be met. Participation solely in the acquisition of funding or the collection of data does not justify authorship. General supervision of the research group is also not sufficient. Any part of an article critical to its main conclusions must be the responsibility of at least one author.

Only those with key responsibility for the material in the article should be listed as authors; others contributing to the work should be recognized separately. Editors may require authors to justify the assignment of authorship.

**Previous presentation.** If the paper has been presented at a meeting, please give the name of the meeting, the location, and the inclusive dates.

**Location of work and address for reprints.** Provide the department, institution, city, and state **where the work was done.** Include a full address for the author who is to receive reprint requests.

**Acknowledgments.** Grant support should be acknowledged in a separate paragraph and should include the full name of the granting agency and grant number. See instructions for Disclosure of Commercial Interests. The *Journal* does not allow acknowledgment of persons involved with the preparation or typing of manuscripts. Acknowledgment of individuals involved with the scientific content of the work should not exceed four typed lines. Drug company support of any kind must be acknowledged.

## Abstract

Authors of review articles must include the following information, under the headings indicated: Objective—the primary purpose of the review article; Method—data sources, study selection (the number of studies selected for review and how they were selected), data extraction (rules for abstracting data and how they were applied); Results—methods of data synthesis, key findings; and Conclusions—including potential applications and research needs. Authors of research articles must include Objective—questions addressed by the study; Method—design of the study, setting (location and level of clinical care), patients or participants (manner of selection and number who entered and completed the study), interventions (if any), main outcome measures (primary study outcome measure as planned before data collection); Results—key findings; and Conclusions—including direct clinical applications. Other types of articles, including Clinical and Research Reports, should include unstructured abstracts.

The abstract is a single paragraph no longer than 250 words for Special Articles and Regular Articles and no longer than 60 words for Clinical and Research Reports.

## Text

**Research design and statistics.** The following information regarding research design should be included: 1) a clearly stated hypothesis, 2) the names of the statistical tests used, 3) whether tests were one- or two-tailed, and 4) what test was used for each set of data. Standard deviations, rather than standard errors of the mean, are required. Statistical tests that are not well known should be referenced. All significant and important nonsignificant results must include the test value, degree(s) of freedom, and probability. For example, "The analysis of variance indicated that those who abstained from coffee had significantly higher course grades than those who did not abstain (F=4.32, df=3, 17, p<0.05)." Reviewers will evaluate the appropriateness of the analyses.

**Abbreviations.** Spell out all abbreviations (other than those for units of measure) the first time they are used. Idiosyncratic abbreviations should not be used.

**Drugs.** Generic rather than trade names of drugs should be used. Trade or manufacturers' names are used only if the drug or equipment is experimental or unavailable in this country or if such information is crucial to the evaluation of the results or replication of the study.

## References

References are numbered and listed by their order of appearance in text; the text citation is followed by the appropriate reference number in parentheses. Do not arrange the list alphabetically. References in tables and figures are numbered as though the tables and figures were part of the text.

References should be restricted to closely pertinent material. **Accuracy of citation is the author's responsibility.** References should conform exactly to the original spelling, accents, punctuation, etc. Authors should be sure that all references listed have been cited in text.

Personal communications, unpublished manuscripts, manuscripts submitted but not yet accepted, and similar unpublished items should not appear in the reference list. Such citations may be noted in text. It is the author's responsibility to obtain permission to refer to another individual's unpublished observations. Manuscripts that are actually "in press" may be cited as such in the reference list; the name of the journal or publisher and location must be included.

Type references in the style shown below, **double-spaced throughout. List all authors;** do not use "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*; journals not indexed there should not be abbreviated.

1. Noyes R Jr, DuPont RL Jr, Pecknold JC, Rifkin A, Rubin RT, Swinson RP, Ballenger JC, Burrows GD: Alprazolam in panic disorder and agoraphobia, results from a multicenter trial, II: patient acceptance, side effects, and safety. Arch Gen Psychiatry 1988; 45:423–428
2. Kaplan HI, Sadock BJ (eds): Comprehensive Textbook of Psychiatry, 4th ed, vol 2. Baltimore, Williams & Wilkins, 1985
3. Fyer AJ, Manuzza S, Endicott J: Differential diagnosis and assessments of anxiety: recent developments, in Psychopharmacology: The Third Generation of Progress. Edited by Meltzer HY. New York, Raven Press, 1987

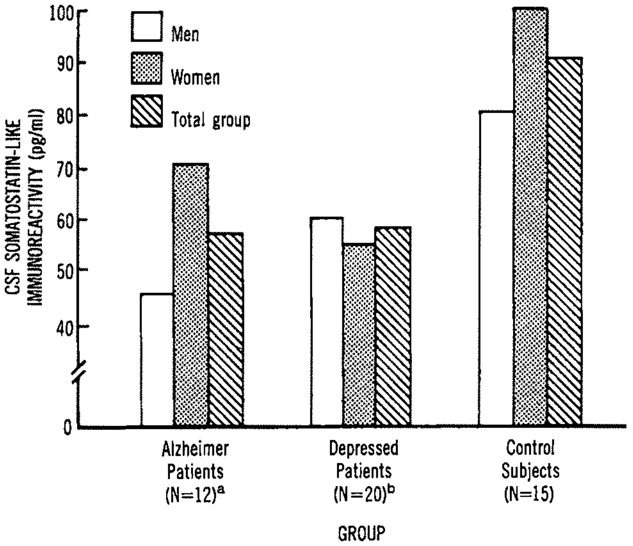
# TABLES AND FIGURES

The *Journal* does not publish tables or figures that have been submitted elsewhere or previously published. Tables and figures that duplicate 1) material contained in text or 2) each other will not be used. Authors will be asked to delete tables and figures that contain data which could be given succinctly in text. Consult recent issues of the *Journal* for format. A double-spaced table or a figure that fills one-half of a vertical manuscript page equals 100 words of text; one that fills one-half of a horizontal page equals 150 words. A copy of each **table and figure must be included with each copy of the manuscript.**

## Tables

**Tables should be double-spaced, no wider than 120 typewriter characters, including spaces, and no longer than 70 lines.** Values expressed in the same unit of measurement should read down, not across; when percentages are given, the appropriate numbers must also be given.

**FIGURE 1. Mean CSF Somatostatin Levels of Patients With Alzheimer's Disease, Older Depressed Patients, and Age-Matched Control Subjects**



[a] Significant difference between men and women (t=1.81, df=10, p<0.05) and between the total Alzheimer's disease group and the total control group (t=2.49, df=25, p<0.01).

[b] Significant difference between the total depressed group and the total control group (t=2.75, df=33, p<0.005).

### Figures

Figures are considered as text and are subject to revision by the authors upon recommendation of the Editors. Figures should, however, be professionally prepared. Glossy or other camera-ready prints should accompany the submitted manuscript. Computer-generated figures that do not meet quality printing standards will be returned for revision. All figure titles and footnotes should be typed and sent together on a separate page.

The *Journal* does publish color illustrations. However, the cost to publish them, including reprint charges, will be the responsibility of the authors. An estimate of the cost will be provided to the authors at the time of first decision.

**Format.** Figures are visual expressions of data trends or relationships. Figures that represent numerical data which could be expressed more succinctly or clearly in tabular form should be converted to tables. Line graphs should show change in continuous variables; comparisons of like values in different groups should be presented as bar graphs.

**Lettering.** Figure type should be sans serif and should be 7 points or larger after the figure is reduced; most figures taking up the width of a vertical manuscript page are reduced to a width of 19.5 picas (3.25 inches), and those requiring a horizontal manuscript page are usually reduced to 40.5 picas (6.75 inches). When space on the horizontal axis is insufficient, headings may be placed diagonally on the axis. Do not use idiosyncratic abbreviations.

**Other.** The following are additional specific requirements. Please refer to the example given above.

1. Do not use solid black shading; rather, include outlined white among shadings.
2. The heading for the vertical axis of a graph should run vertically along the axis, not horizontally at the top or bottom. Headings for the horizontal axis should appear below that axis, not at the top of the graph.
3. Error bars should not be used.
4. Do not extend the vertical or horizontal axis of a graph beyond the point needed for the data shown.
5. In a graph comparing different groups of subjects, the number of subjects in each group should appear with the name of the group—in the key, in the headings below the horizontal axis, or in the title.
6. To save space, related figures that have the same vertical or horizontal axis should be combined and identified with internal headings.
7. The key should appear within or above the figure but should not widen the figure. Avoid placing other type (e.g., number of subjects, statistical values) within a graph.
8. Footnotes (including p values) should be cited with superscript letters in the title or in the axis labels and should be listed in the order in which they are cited in the figure.
9. Multiple figures for the same article should be prepared as a set, and the type should be approximately the same size after reduction.

## PROCESSING OF ACCEPTED MANUSCRIPTS

Manuscripts are accepted with the understanding that the Editor and the editorial staff have the right to make revisions aimed at greater conciseness, clarity, and conformity with *Journal* style. Accepted papers will be edited and sent to the corresponding author for corrections and answers to editorial queries. **No proofs are sent to authors.** Authors who will be away from their offices for a long period or who change address after notification of acceptance should inform the *Journal* staff.

## PERMISSION TO REPRINT

Written permission to reprint material published in the *Journal* must be secured from the APA Periodicals Services Division, 1400 K Street, N.W., Washington, DC 20005; telephone: (202)682-6156. There is usually a charge for such permission, except for nonprofit classroom or library reserve use by instructors and educational institutions or for authors who wish to reprint their own material.

## REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to the corresponding author before publication of the paper. The printer usually mails reprints approximately 6 weeks after the article has been published. Reprints of items in the Book Forum and Letters to the Editor sections are not available.

## *Chair, Department of Psychiatry*

Candidates for this position must have demonstrated leadership ability and administrative experience in an academic health center. Candidates must have an an academic background suitable for the award of tenure at the University of Massachusetts Medical School.

The Department of Psychiatry has major teaching responsibilities in the first two years of the medical school curriculum as well as in a required clerkship and elective programs taken in the clinical years. Well developed, successful residency programs in general and child psychiatry are in place.

It is important that candidates provide leadership for the development of a nationally prominent research program in the neurosciences. The Medical Center is planning expansion of research space and clinical facilities in psychiatry.

The Department has a major role in public sector psychiatry within the Commonwealth, and it is expected that the Chair will have a personal philosophy compatible with this departmental commitment. The Department is also responsible for delivery of a wide range of outpatient psychiatric and psychological services to adults and children and for several adolescent and adult inpatient units, both at the Medical Center and in the public sector.

**Women and minority candidates are encouraged to apply. Send curriculum vitae to Neil R. Blacklow, M.D., Chairman, Psychiatry Search Committee, Department of Medicine, University of Massachusetts Medical Center, Worcester, MA 01655. The University of Massachusetts Medical Center is an Equal Opportunity/Affirmative Action Employer.**

## PSYCHIATRIST

We seek a full-time Psychiatrist, (board-eligible/board-certified and Texas Medical license required), for one of the largest community-based MHMR Centers in Texas, located in the Capitol City.

Position will provide clinical leadership, diagnosis, treatment and teaching in a multidisciplinary setting. The Center is one of 10 national demonstration projects for the Robert Wood Foundation.

We offer an excellent comprehensive benefit package, malpractice insurance, AMA and APA dues, and one week paid CME.

Salary begins at $93,531 and is negotiable; augmentation for appropriate experience is also negotiable.

Austin is a city with outstanding cultural, educational, and outdoor opportunities located in the beautiful Texas hill country.

Submit CV to:

**Austin-Travis County**
**Mental Health/Mental Retardation Center**
**1430 Collier Street**
**Austin, TX 78704**
**(512) 440-4072**
**Attn: Personnel Department**

**EOE**

---

## CLINICAL POSITIONS

As part of an expansion of its clinical and clinical research programs, Stanford University is recruiting several psychiatrists to fill positions in the following areas:

I. Consultation/Liaison Service (2 positions)
II. Acute Inpatient Service
III. Combined Inpatient/Outpatient Mood Disorders Service (2 positions)

Responsibilities will include providing clinical service, teaching medical students, residents and fellows in psychiatry and in some cases, participating in ongoing clinical research. The applicant for each position must demonstrate clinical competence, teaching experience and a commitment to scholarly advancement in the filed. Positions are available on both the University tenure track as well as the Medical Center clinical track. Demonstration of research experience and productivity is required for the University tenure track positions(s).

Applicants must be board eligible or board certified in psychiatry.

Stanford University is committed to increasing representation of women and members of minority groups in its faculty and particulary encourages applications from such candidates. Salary and rank are dependent upon qualifications.

Applicants should forward a curriculum vitae and the names of three references to:

***Alan F. Schatzberg, M.D., Chairman***
***Department of Psychiatry and Behavioral Sciences***
***Stanford University School of Medicine***
***Stanford, California 94305***

**The Medical College of Georgia**
**Department of Psychiatry and Health Behavior**
**is seeking a**

**DIRECTOR OF OUTPATIENT PSYCHIATRY**

The Psychiatry Department at the Medical College of Georgia is in the process of recruiting a group of new faculty for key positions in its sections. A search committee is now seeking a Director of Outpatient Psychiatry for appointment in the School of Medicine, available July 1, 1992. Applicant must be a board eligible or certified psychiatrist with leadership skills in integrating clinical and research goals in an outpatient setting. Previous experience in managing public or private outpatient administrative systems is also desirable. Appointment will be to a full time academic faculty position with academic rank and salary commensurate with background and qualifications. Please send CV and 3 letters of reference to:

**Jeffrey Rausch, M.D.**
**Professor and Vice Chairman**
**Department of Psychiatry and Health Behavior**
**The Medical College of Georgia**
**Augusta, GA 30912-3800**

# CONTEMPORARY STRATEGIES FOR DEPRESSION MANAGEMENT

## Tuesday, May 5, 7:00–10:00 pm
## Independence Ballroom
## Grand Hyatt, Washington, D.C.

*Hors d'oeuvres beginning at 6:00 pm in the Independence Ballroom Foyer; desserts and coffee immediately following the symposium*

This symposium will help clinicians understand the pharamcokinetic and pharmacodynamic profiles of antidepressant agents. Recognizing these effects may allow for optimal therapy for depression. Topics include the merits of both psychotherapy and psychopharmacologic intervention, overview of the management of depression, and evaluations of available agents.

### Chairman and Moderator

Herbert Pardes, M.D.
Vice President for Health Sciences
Dean, Faculty of Medicine
Professor and Chairman, Department of Psychiatry
College of Physicians and Surgeons of Columbia University
New York, NY

### Tailoring Treatment: Pharmacologic Issues

Sheldon H. Preskorn, M.D.
Professor and Vice Chairman
Department of Psychiatry
University of Kansas School of Medicine
Director, Psychiatric Research Institute
St. Francis Regional Medical Center
Wichita, KS

### Side Effects of Selective Serotonin Reuptake Inhibitors

Walter Brown, M.D.
Associate Professor of Psychiatry
Brown University School of Medicine
Providence, RI

### Approaches to Depression Management

Joseph Mendels, M.D.
Professor of Psychiatry and Human Behavior
Professor of Pharmacology
Thomas Jefferson University
Medical Director
Philadelphia Medical Institute
Philadelphia, PA

### Pharmacotherapy vs. Psychotherapy + Pharmacotherapy: A Debate

Jan A. Fawcett, M.D.
Professor and Chairman
Department of Psychiatry
Rush–Presbyterian–St. Luke's Medical Center
Chicago, IL

Myrna Weissman, Ph.D.
Professor of Epidemiology in Psychiatry
College of Physicians and Surgeons of Columbia University
Chief, Division of Clinical-Genetic Epidemiology
New York State Psychiatric Institute
New York, NY

The American Psychiatric Association (APA) is accredited by the Accreditation Council for Continuing Medical Education to sponsor continuing medical education for physicians.

The APA designates this continuing medical education activity for 3 credit hours in Category I of the Physician's Recognition Award of the American Medical Association and for the CME requirement of the APA.

Supported by an educational grant from Pfizer **Roerig**

PATIENT CARE FOR THE 21ST CENTURY: ASSERTING PROFESSIONAL VALUES WITHIN ECONOMIC CONSTRAINTS

THE AMERICAN JOURNAL OF PSYCHIATRY

*Editorial*

# New Year's Greetings

We recently had occasion to inspect an early edition of Dr. Johnson's famous *Dictionary,* and, our eyes falling on the entry for "Editor," read it as "He that reviles any work for publication." A second, more careful look at once revealed our perceptual error: We had mistaken one of those archaic eighteenth-century lower-case "s's" for an "l" and had fallen victim to a striking example of editorial "projective counteridentification." Although there is often much truth in unconscious mechanisms, editors are perhaps not always so arbitrary in their decisions as suffering authors perceive them; their biases are strictly controlled if not totally dispelled by the concerted advice of the multitude of informed colleagues whom they consult as expert reviewers. We (and our authors) must, therefore, proclaim our heartfelt appreciation to the following large community of scholars who have kept us on the strait and narrow path of editorial objectivity during the period from October 1, 1990, to October 31, 1991:

Larry Abel, Ph.D.
Steven L. Ablon, M.D.
Richard Abrams, M.D.
Sigurd H. Ackerman, M.D.
Christine Adams, M.D.
Paul L. Adams, M.D.
Gerard Addonizio, M.D.
C. Alex Adsett, M.D.
W. Stewart Agras, M.D.
Renato D. Alarcon, M.D., M.P.H.
C. Knight Aldrich, M.D.
Norman E. Alessi, M.D.
George S. Alexopoulos, M.D.
Murray Alpert, Ph.D.
Kenneth Z. Altshuler, M.D.
Jambur V. Ananth, M.D.
Arnold Andersen, M.D.
Douglas Anderson, M.D.
William H. Anderson, M.D.
Michael A. Andrykowski, Ph.D.
Burton M. Angrist, M.D.
Ann H. Appelbaum, M.D.
J. Arboleda-Florez, M.D.
Stephan Arndt, Ph.D.*
Robert L. Arnstein, M.D.
Stuart S. Asch, M.D.
Gregory Asnis, M.D.
Boris M. Astrachan, M.D.
J. Hampton Atkinson, M.D.
David Avery, M.D.
Efrain C. Azmitia, Ph.D.

Leona L. Bachrach, Ph.D.
Ross J. Baldessarini, M.D.
George U. Balis, M.D.

---

**Deceased.

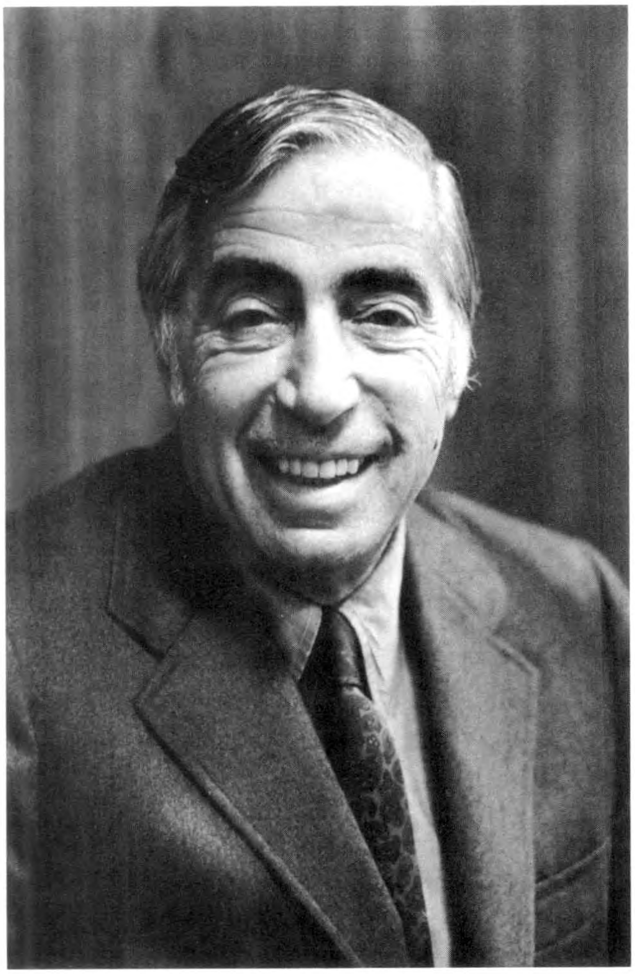
1991 has been a year of consolidation and progress for the *Journal.* Ms. Sandra Patterson, who assumed the Managing Editorship as 1990 ended, has firmly grasped the editorial helm, and with the unflagging help of her Assistant Managing Editor, Ms. Linda Loy, and her entire editorial staff, has introduced modern techniques of electronic publishing that have already made the production of the *Journal* more efficient and economical while markedly increasing our editorial control over the quality and accuracy of its pages. We must also express our deep gratitude for the help and companionship of our Deputy Editor, Dr. Nancy C. Andreasen, our Statistical Editors, Drs. John J. Bartko and Lee Gurel, and our thirteen Associate Editors; quietly, consistently, and selflessly given, their contributions are ever invaluable. Our sadness at losing Drs. T. Byram Karasu and Judith L. Rapoport, whose terms as Associate Editor expired at the end of the 1991 Annual Meeting, has been tempered by welcoming Drs. Gabrielle A. Carlson and David Spiegel to the Editorial Board. *Ave atque vale!*

During a year when our Association, like the world at large, has been plagued by fiscal problems, we are particularly grateful for the strong support and guidance of the Medical Director, Dr. Melvin Sabshin, and his staff, and to the Board of Trustees for their perception and understanding of the *Journal*'s needs. For their help in many matters large and small we must also express our appreciation to Drs. Robert J. Campbell III, John Hamilton, William A. More, Harold A. Pincus, Carolyn B. Robinowitz, Jeanne Spurlock, John A. Talbott, and Jack W. White; to Mses. Laura Abedi, Teddye Clayton, Carol Davis, Elizabeth Flynn, Nancy Frey, Debbie Goldberg, Alison Jones, Joan Lefkowitz, Karen Loper, Beth Prester, Arlis Richardson, and Jacqueline Young; and to Messrs. William E. Baxter, John Blamphin, George Campbell, Herbert M. Gant, Joel Klein, Ronald McMillen, Raymond J. Purkis, Jr., and Michael Roy.

As 1991 disappears astern, lashed to our masthead we wish all our colleagues and readers a safe and happy passage through whatever tempests of *glasnost* and *perestroika* still blow ahead.

J.C.N.

# In Memoriam



## John Paul Spiegel, M.D.
## 1911–1991

John P. Spiegel, the 103rd President of the American Psychiatric Association, died on July 17, 1991, at his home in Cambridge, Mass.

Dr. Spiegel was born in Chicago on March 17, 1911. He was a member of a well-known family that was prominent in community affairs and the business world. He graduated from Dartmouth College in 1934 and then entered Northwestern University Medical School, graduating in 1938. From 1938 to 1940 he had an internship at Michael Reese Hospital and a residency at that institution from 1940 to 1942. In 1942 he became a psychiatric consultant to the 12th Army Air Force in the Mediterranean Theatre of Operations. From 1944 to 1946 he was Chief of Professional Services of the Army Air Force Convalescent Hospital in St. Petersburg, Fla., and Chief of Psychiatric Services at Fort George Wright in Spokane, Wash.

Upon his completion of military service he returned to Michael Reese Hospital, where he was Chief of the Psychiatric Clinic from 1946 to 1951. He graduated from the Chicago Institute for Psychoanalysis in 1949 and was certified by the American Board of Psychiatry and Neurology in the same year. He also was an Associate Attending Physician at the Cook County Psychopathic Hospital in Chicago from 1947 to 1949. Dr. Spiegel was on the faculty of the University of Chicago School of Social Service Administration from 1949 to 1951. From 1951 to 1954 he was the Associate Director of the Institute for Psychiatric and Psychosomatic Research and Training at the Michael Reese Hospital. In 1953 he joined the faculty of the Department of Social Relations of Harvard University. He progressed there from Lecturer to Associate Clinical Professor of Psychiatry until 1966, when he became the Director of the Lemberg Center for the Study of Violence and Professor of Social Psychiatry of the Florence Heller Graduate School for Advanced Studies in Social Welfare at Brandeis University in Waltham, Mass. From 1973 to 1976 Dr. Spiegel was involved with the Family Transactions Project at Brandeis University, and from 1977 to 1980 he was the Director and Principal Investigator of the NIMH-funded Training Program in Ethnicity and Mental Health at the Heller School. In 1983 he became Adjunct Professor of Cultural Psychiatry at the University of Massachusetts Medical Center in Worcester.

Dr. Spiegel's outstanding career has been detailed because it illustrates the versatility and direction of his professional trajectory. He intimately worked with outstanding colleagues at Michael Reese Hospital—Roy Grinker, Sr., David Hamburg, Melvin Sabshin, Don Oken, and many other colleagues. These individuals have gone on to develop their own outstanding careers. Dr. Spiegel was farsighted in understanding, working in, teaching, and investigating areas of psychiatry that were at the time not the mainstream of our specialty. However, his pioneering path-making and leadership roles in various organizations have yielded very positive results as seen in the directions psychiatry is taking today—e.g., academic commitment, interdisciplinary research, and social and cultural psychiatry.

Dr. Spiegel was President of our Association from 1974 to 1975. He served with distinction on the Committee on Civil Defense (1955–1958); chaired the Task Force on Aggression and Violence (1969–1972); was a member of the Task Force on Third-Party Intervention in Community Conflict (1973–1974), the Committee on Interprofessional Services (1974–1978), the Commission on Standards and Practices of Third-Party Payments (1974–1977), and the Council on National Affairs (1977–1982); and was chairperson of the Task Force on Ethics and Cultural Issues in Psychiatry (1978–1980).

In addition, he was President of the American Academy of Psychoanalysis (1982–1983); the organizer and founder of the American Family Therapy Association; a member of the American Physicians Fellowship for the Israel Medical Association, the Sections on Medical Sociology and Family Sociology of the American Sociological Society, and the Board of Directors of the Foundations' Fund for Research in Psychiatry (1960–1965); and President of the Mental Health Film Board (since 1978), as well as a member of many other outstanding groups with whom he was actively involved.

His voluminous writings include such outstanding contributions as *Men Under Stress,* written with Roy R. Grinker, Sr., and many papers and books in other areas of our discipline. His published contributions covered such areas as acute stress, the family, emotional reactions to catastrophe, panic, systems theory, conflict resolution, cultural variations in attitudes toward death and disease, communications theory, psychoanalysis and psychotherapy, violence, terrorism, riots, peer review, generational conflicts, videotape techniques in psychiatric training and treatment, and the cultural aspects of the case of Anna 0. He published over a hundred papers and several books, some of which are now classics.

John Spiegel was a psychiatrist who was on the horizon of many now accepted areas of our field, when the dawn was just breaking. He was very interested in Pacific Rim and South Pacific cultures and was a founder of the Pacific Rim College of Psychiatrists.

In addition to all of his outstanding work on behalf of humane endeavors, he was married to Babette Shiller, an author and advocate of prison education. She died in 1975. Dr. Spiegel also had three daughters, a son, and eight grandchildren. Dr. Spiegel's pertinent contributions are very useful to us today as we confront many issues he insightfully addressed in his writings and presentations. It is with great appreciation that his colleagues and friends will know more of what he did for our Association, for psychiatry, and for our culture and society when they can view his work in a past life course perspective. He will be missed.

GEORGE H. POLLOCK, M.D., PH.D.

# The Meaning of Expressed Emotion: Theoretical Issues Raised by Cross-Cultural Research

Janis H. Jenkins, Ph.D., and Marvin Karno, M.D.

*The finding that expressed emotion is associated with the course of psychiatric disorder has generated a great deal of clinical and research interest in expressed emotion as an important risk factor. Theoretical elucidation of the construct of expressed emotion has lagged considerably behind this interest, however. The authors contribute to a dialogue on what is inside the "black box" called expressed emotion. They argue that cross-cultural research can provide an empirical basis for the theoretical grounding of expressed emotion factors. A comparative approach reveals that the construct of expressed emotion is essentially cultural in nature. The constellation of emotions, attitudes, and behaviors that are indexed by the expressed emotion method represent cross-culturally variable features of family response to an ill relative. Questions surrounding the cultural validity of the construct of expressed emotion, the qualitative dimensions of expressed emotion, and statistically significant cross-cultural variations in expressed emotion profiles are discussed. Finally, the authors provide an outline of diverse (cultural, psychobiological, social-ecological) features of expressed emotion. Anthropological analysis of expressed emotion reveals that although expressed emotion indexes a Pandora's box of diverse features, culture provides the context of variation through which these factors are most productively analyzed.*

(Am J Psychiatry 1992; 149:9–21)

Expressed emotion is currently among the most thoroughly investigated psychosocial research constructs in psychiatry (1–4). Developed some three decades ago by George Brown and his colleagues in England, the term "expressed emotion" refers to a global index of particular emotions, attitudes, and behaviors expressed by relatives about a family member diagnosed with schizophrenia. The specific factors that make up the construct of expressed emotion are criticism, hostility, and emotional overinvolvement. Several naturalistic studies have demonstrated the association of these factors with clinical relapse (5–8). Patients living in home environments characterized by high levels of expressed emotion are significantly more likely to experience a clinical relapse than are patients residing in households with low levels of expressed emotion. This finding has not surprisingly resulted in a great deal of clinical interest in a construct originally developed for purposes of basic research (9–12).

Theoretical elucidation of this research construct has lagged considerably behind clinical interest in expressed emotion. As Koenigsberg and Handley (13) observed in 1986, the elusive theoretical and empirical bases of the construct have gone unexamined. Precisely what is inside the "black box" called expressed emotion has

somehow remained mysterious, as has been widely acknowledged (14, 15). In 1989 Vaughn (15), one of the principals of expressed emotion research, highlighted the fact that "substantial questions remain about the nature and meaning of the global expressed emotion index" (p. 2). This theoretical impoverishment provides a formidable research dilemma: ***the problem of prediction without understanding*** (16). The purpose of this paper is to provide a theoretical elucidation of the construct of expressed emotion, originating at the interface between anthropology and psychiatry. In our view, this analytic perspective is particularly suited to the task, since it is primarily in a cross-cultural, comparative light that the critical questions appear concerning the theoretical status of expressed emotion. Why have such striking differences in expressed emotion been observed across diverse populations and what can these differences tell us about the nature of the construct? What features, if any, do the specific components of expressed emotion have in common?

Any adequate theoretical elucidation must take into account the essentially cultural basis of the construct of expressed emotion. Culture can be defined as a generalized, coherent context of shared symbols and meanings that individuals dynamically create and recreate for themselves in the process of social interaction. In everyday life, culture is something people come to take for granted—their way of feeling, thinking, and being in the world—the unself-conscious medium of experience, interpretation, and action. Culture is thus the most generalized baseline from which individuals may deviate, an invaluable baseline for comparative studies of psychopathology. Specific attitudes and behaviors—recorded in the form of criticism, hostility, and emotional overinvolvement—are cultural dimensions of family response to and interpretation of what is professionally diagnosed as schizophrenic illness (4). In other words, what counts as criticism, hostility, and emotional overinvolvement is a matter of cultural definition.

Psychological anthropologists have shown that emotion can no longer properly be considered a private, intrapsychic, or psychobiological phenomenon. Instead, emotions—no less than other attitudes, beliefs, and behaviors—are substantially mediated by culture (17–20). To be specific, a culture provides its members with an available repertoire of affective and behavioral responses to the human condition, including illness. In addition, it offers models of how people should or might feel and act in response to the serious illness of a loved one. This may involve anger and hostility in one context or sadness and sympathy in another. The expressed emotion index is properly regarded as measuring cultural features because it taps a set of shared meanings and patterns of affective response to the problem of living with schizophrenic illness in a family setting.

Most important is consideration of critical comments, since this component accounts for the vast majority of what is really being measured by the construct of expressed emotion. Hostility and emotional overinvolvement are lesser variables of the expressed emotion triad and have been empirically observed far less frequently. Criticism within Anglo-American family settings, for example, may focus on allegations of faulty personality traits (e.g., laziness) or psychotic symptom behaviors (e.g., strange ideas). However, in other societies, such as those of Latin America, the same behaviors may not be met with criticism (21). Among Mexican-descent families, for example, criticism tends to focus on disrespectful or disruptive behaviors that affect the family but not on psychotic symptom behaviors and individual personality characteristics. Thus, culture plays a role in creating the content or targets of criticism. Perhaps most importantly, culture is influential in determining *whether* criticism is a prominent part of the familial emotional atmosphere.

The cross-cultural validity of the factors of expressed emotion necessarily requires close attention to indigenous definitions and expressions of criticism, hostility, and emotional overinvolvement (4). Are these affective domains observable in social interaction? Are they communicated in generally recognizable ways through language, paralanguage, and actions? Based on data generally available in ethnographic accounts, our own view is that verbal criticism within families is likely to occur in most of the world's cultures. For example, criticism has been noted in such geographically diverse groups as the Pintupi aborigines of Australia (22) and the Inuit Eskimos (23). Nevertheless, we would also expect a great deal of cross-cultural variation in the frequency, intensity, nature, and meaning of criticism within families. In the light of variations in social structure, household organization, and cultural constructions of the self, we might expect emotional overinvolvement to be less common across cultures. However, there appear to be some types of behavior reflecting emotional overinvolvement among the Inuit Eskimos (24), for example. Certainly the basic features of emotional overinvolvement are commonly encountered in clinical practice in Europe, Latin America, Australia, and North America. The cross-cultural applications and likely limitations of the construct of emotional overinvolvement are matters for empirical demonstration.

In the absence of such empirical testing, it would be a mistake to conclude that expressed emotion factors are a priori culture-bound to British or Anglo-American families. The family factors themselves are neither culture-bound nor ethnocentric; it is the cultural validity of their application that must concern us. Evidence for expressed emotion factors has definitively been found —in culturally specific ways—in British, Mexican-descent, and Anglo-American contexts. Further studies of the frequency and distribution of the basic elements of the expressed emotion index—as well as an interpretation of their nature and meaning—are suitably the subject of inquiry. In the absence of adequate data on this subject, it remains to be seen whether societies exist in which a complete absence of these factors can be documented. Given the common context of families living with the difficulties generated by schizophrenic illness, it is reasonable to expect some cross-cultural similarities in the kinds of things relatives might find objectionable and therefore deserving criticism. Given variations in cultural definitions of behavior and emotion, however, it is also reasonable to expect substantial differences in the things family members feel they can appropriately tolerate. Thus, the research domain of criticism clearly requires a cross-cultural perspective.

## THE CULTURAL AND CLINICAL EXPORT OF EXPRESSED EMOTION

In the last 10 years alone, well over 100 English-language journal articles on expressed emotion have appeared. Popular topics include the role of expressed emotion in the course of schizophrenia (5–8), family treatment (9, 25), correlative or "streamlined" measures of expressed emotion (26–29), and vigorous protests by relatives in the United States who perceive researchers as indicting them for causing or maintaining their family member's illness (30). As an outcome measure associated with the clinical course of illness, expressed emotion has been applied across a variety of cultural and clinical groups. Indeed, the study of expressed emotion has become an international preoccupation traversing five continents. Research is complete or underway in Europe (England [4, 5, 31, 32], Denmark [33], Italy [34], France [35], Spain [unpublished paper by E. Gutierrez], and Germany [36]), North America (among Anglo-Americans [7], those of Mexican descent [8], and African-Americans [37]), Asia (Taiwan [38]), India (33, 39, 40), North Africa (Egypt [personal communication from A. Wilson]), and Australia (41). Moreover, although this work was initially restricted to schizophrenic populations, the study of expressed emotion has assumed new applications in research for both psychiatric and nonpsychiatric conditions. Studies have been conducted on affective disorders such as depression (42) and bipolar illness (43), dementia (44), anorexia nervosa (45), asthma (46), stroke (47), obesity (48), and intractable childhood epilepsy, autism, Parkinson's disease, and inflammatory bowel disease (15). To summarize, studies of expressed emotion have been applied to a variety of both cultural and clinical populations.

It is not our purpose here to review the status of the now numerous expressed emotion replication studies; summaries and critical reviews of these findings are available elsewhere (13, 49). We simply note here that although many investigators found support for the association between expressed emotion and outcome (41), others failed to confirm this relationship. For example, one controlled intervention trial that focused on medication-compliant patients found no association between expressed emotion or controlled dosage and clinical outcome (50). That some of these findings might constitute an empirical challenge to the confirmatory studies is compromised by these investigators' use of divergent, or even flawed, methodological procedures (32–36; unpublished manuscript of E. Gutierrez). For example, Mintz et al. (51) reported that the negative results of a study by MacMillan et al. (32) do not constitute a legitimate challenge to the relationship of expressed emotion to clinical relapse because the statistical analyses used by MacMillan et al. were inappropriate.

As summarized by Vaughn (15), the North American replications of the earlier British studies by Brown and his colleagues were "distinguished by their comparable approaches to diagnosis, expressed emotion assessment, and the definition of relapse as the return or exacerbation of specifically schizophrenic symptoms" (p. 15). Since these studies retained methodological consistency of approach across these different populations, they constitute a first step toward consideration of the cross-cultural relevance of expressed emotion. We proceed on the assumption that the relevance of expressed emotion to the course of illness has satisfactorily been demonstrated and that the relationship between expressed emotion and relapse has been replicated more often than not (52). Therefore, although individual variability and complexity in the salience of the association between expressed emotion and outcome exist, expressed emotion is appropriately regarded as a major risk factor in the course of a psychiatric illness (15, 49, 53).

## THE THEORETICAL STATUS OF THE CONSTRUCT OF EXPRESSED EMOTION

It might seem reasonable to assume that the proliferation of expressed emotion research is based on the empirical testing of an articulated set of assumptions concerning the theoretical status and parameters of the construct. Unfortunately, this does not reflect the current situation. We need to know what expressed emotion is measuring or tapping. In the absence of such an understanding, expressed emotion research endeavors are at risk of becoming repetitive and mindless exercises without meaning.

Several factors seem to have contributed to this state of affairs. First, the refined and systematic measurement techniques have focused on specific components of expressed emotion (criticism, hostility, and emotional overinvolvement). This focus is reasonable in the wake of research results implicating expressed emotion in relapse (5–8). The very specificity of this empirically derived global construct seems to have diverted scientific interest in a broader understanding of the nature of expressed emotion.

Second, expressed emotion summarizes a seemingly disparate constellation of family affects, attitudes, and behaviors. It is not immediately obvious just how or why these factors cohere or should be examined together. In fact, these features of family interaction do not necessarily go together conceptually. The perhaps infelicitous coding and labeling of what has come to be known as expressed emotion have happened by empirical accident.

Third, because of the microanalytic rating technique and highly specific empirical focus of expressed emotion research, attention has been diverted from questions concerning the validity of what is being measured. This shortcoming is by no means unique to expressed emotion research but is true of empirical psychiatric research endeavors more generally. As part of a paradigmatic definition of the pertinent research questions and methods for their investigation, psychiatric research efforts today typically do not prominently concern questions of validity, interpretation, or meaning (54). In the case of expressed emotion research, this presents a problem because explication of expressed emotion, as an empirical index of relatives' subjective experience and response, requires a theoretical bridge from behavior to meaning.

The theoretical issue that has garnered the most attention—the question of how expressed emotion might influence the clinical course of illness—remains largely unelaborated. The working assumption, largely unchanged over the past two decades, is that emotional arousal constitutes a major stressor for persons with schizophrenic illness. Overarousal through exposure to high degrees of negative affects, the theory asserts, may result in relapse or exacerbation of florid symptoms (5, 6). In 1987, Kuipers (2) summarized the physiological evidence for this assertion as inconclusive. An understanding of the physiological aspects of expressed emotion requires further research (17, 49) but is not our principal concern here. Our interest lies instead with the cultural and psychosocial status of the construct of expressed emotion on the grounds that it is insufficient merely to link expressed emotion with relapse.

## CLUES TO THE NATURE OF EXPRESSED EMOTION

According to Brown (3), the search for the family factors that ultimately came to be known as the expressed emotion construct originated with an interest in the everyday features of family life. He reported that he and his colleagues assumed that anything of importance was to be found in nonpathological communications rather than in presumed pathological family features. This emphasis on the ordinary was conceptualized as a shift away from psychiatric assumptions, current in the 1950s, that psychopathological family features held etiological significance for schizophrenia.

Despite the shift in emphasis from etiology to course of illness, the British focus on family factors was deeply influenced by the long research tradition in North American psychiatry of studying schizophrenia in relation to family factors and communication. The underlying premise of expressed emotion research—that emotion is an atmosphere that permeates interactive settings—was pioneered by Harry Stack Sullivan (55). The empirical investigation of particular family affects by the British researchers represented further developments of the research traditions initiated by Bateson et al. (56), Wynne et al. (57), and Lidz and Fleck (58). Even so, there are no directly equivalent concepts in the family psychopathology literature for the specific features that make up the construct of expressed emotion. Criticism, a prosaic feature of family communication, is by no means restricted to families of individuals with schizophrenia, and criticism is of a different order than etiological notions such as double-bind, pseudo-mutuality, and schism. The factor of emotional overinvolvement would appear most closely to approximate dimensions of intrusiveness as investigated by Lidz and Fleck (58). Their studies of family relations claimed an inordinate intrusiveness of parents toward their disturbed offspring. In contrast to these researchers' claim that such features typified disturbed families, the emotional overinvolvement factor has not been empirically observed with great frequency in families of individuals with schizophrenia.

Although the etiological framework of these studies was appropriately discarded for lack of empirical evidence, these early family studies served to identify the kind of material out of which the specific expressed emotion factors were formed. Conceived by Brown and his colleagues as variables that might prove important to the course of an established schizophrenic illness, particular family affects that could potentially influence an often sensitive and fragile process of adaptation to the social world were sought. A strength of the expressed emotion research tradition is its contribution toward the reliable operationalization of such factors with greater precision than had previously been established (59; unpublished 1978 manuscript of G. Brown et al.).

Differences between high and low expressed emotion profiles provide clues to the nature of expressed emotion. In general, explanations of such differences have not progressed beyond the basic hypothesis of Brown et al. some two decades ago (5). This general formulation holds that varying levels of expressed emotion are linked to relatives' own personality traits, to degrees of patient psychopathology, or to a combination of these factors. Hooley (14) argued that differences in expressed emotion are linked to the tendency of relatives to attribute blame to either the patient or the illness and that these attributions can serve as indexes of relatives' personality characteristics. The contribution of differing levels of patient psychopathology has been examined through analyses of the relationship between expressed emotion and the severity of patients' symptoms. Levels and types of patient morbidity have been investigated by severity of symptom scores and behavioral disturbances (symptoms of irritability, destructiveness, suicidality, and bizarre behavior) (6). Results of these analyses have shown expressed emotion to be independent of measures of patient psychopathology and behavioral disturbance (5–8). Expressed emotion as a behavioral manifestation of actual ongoing family interaction has also been confirmed (49, 60).

A refined qualitative analysis of differences in expressed emotion profiles has been provided by Vaughn (61). She systematically identified four factors that differentiate relatives with low versus high expressed emotion: 1) respect for patients' relationship needs, 2) attitudes toward the legitimacy of the illness, 3) level of expectations for patients' functioning, and 4) emotional reactions to the patient's illness. For instance, a British relative is rated low in expressed emotion if he or she displays respect for the patient's need for interpersonal distance, considers the illness to be outside of the patient's control, maintains few expectations for normal functioning, and manifests a concerned but "cool," "easygoing," or "flexible" response to the problem (62, pp. 117–118). The four domains identified by Vaughn are useful in accounting for observed variations in family response and provide an important step in the development of a broader conceptual model of expressed emotion. However, Leff and Vaughn (62), citing their experience in studies in London and Southern California, claimed that "these differences hold across cultures and across diagnostic groups" (p. 112). This sweeping generalization cannot be sustained on the basis of only two English-speaking cultures.

Although the qualitative factors identified by Vaughn provide valuable guidelines for analysis of intracultural variability in expressed emotion, there are several ways in which we can anticipate that culturally distinct features will also come into play. For example, that such dispassionate traits as remaining "cool" or "easygoing" are highly valued in British culture is well-known; it is nonetheless evident from an anthropological point of view that this culturally specific interpretation of low expressed emotion cannot be expected to apply cross-culturally (4).

Greenley (63) has developed an additional scheme for conceptualizing expressed emotion. He proposed broad parameters for expressed emotion as high-intensity interpersonal social control. In Greenley's formulation, the dominant affects of anxiety and fear on the part of relatives lead them to attempt to control the patient socially through criticism and overinvolvement. Relatives who identify the problem as one of mental illness are hypothesized to have a reduced fear/anxiety reaction and therefore a lesser need for high-intensity interpersonal social control (i.e., expressed emotion). This basically social conceptualization provides us with an interesting but partial explanation. The complex of connections between motivation and action in the form of social control necessarily entails a broad array of cultural, psychological, and contextual levels of explanation. As Greenley's analysis illustrates, anxiety and fear may not be the dominant sentiments that motivate particular relatives. We can suggest many more, such as anger, sadness, despair, shame, and guilt, that may be prominent. Indeed, motivating affects can be expected to vary cross-culturally.

Moreover, sizable numbers of Mexican-descent and Anglo-American relatives feel a range of dysphoric affects—including anxiety and fear—despite their belief that their relative is afflicted with a mental illness. For example, Anglo-American relatives may see the problem as one of schizophrenia or negatively valued personality traits (e.g., laziness). Either of these may be regarded as the sole problem or both may be considered in tandem. These relatives may concede that disease may well be present, but they might also feel that certain negative personality traits are present as well (64). The cultural perception that undesirable personality traits are involved is related to core American values such as responsibility, autonomy, independence, and initiative (21). This suggests a more complicated and contradictory chain of cultural logic for interpreting and responding to the illness.

## CROSS-CULTURAL APPROACHES IN EXPRESSED EMOTION RESEARCH

To illustrate the cross-cultural variability of expressed emotion, we examined the results of published studies using comparable methodological techniques. The studies compared are the British studies by Brown et al. (5) and Vaughn and Leff (6), the study of Anglo-Americans in Southern California by Vaughn et al. (7), our group's study of Spanish-speaking subjects of Mexican descent (8, 21), and the study of Hindi-speaking Indians by Wig et al. (33, 39, 40). The latter study was part of the 12-country international World Health Organization (WHO) study of determinants of outcome in schizophrenia. Only two settings in the WHO study were chosen as sites for concurrent expressed emotion studies: Aarhus, Denmark, and Chandigarh, North India. As reported by R. Day (unpublished 1982 paper), logistic and methodological difficulties in carrying out the Danish study apparently render the data problematic for comparative purposes. In this section, we focus on the Indian and Mexican-descent studies because these provide a greater cross-cultural contrast than the English-speaking British and Anglo-American samples.

The following summary points (which apply to the British and Anglo-American studies as well) can be made concerning the Mexican-descent and Indian studies. First, both the Mexican-descent and Indian outcome studies suggest the importance of the family emotional milieu in the course of schizophrenia. Second, analyses of these cross-cultural data establish significant differences in levels of family display of criticism with respect to schizophrenic illness. Third, these data shed light on previous results concerning observed sociocultural variation in schizophrenic outcome, as documented by the WHO International Pilot Study of Schizophrenia (IPSS) (65).

### *Mexican-Descent Study: Expressed Emotion in Southern California*

Although the study of expressed emotion among Anglo-Americans in Southern California (7) constitutes an important replication of the earlier British studies, we believe that the issue of cross-cultural replication could be better addressed through the more culturally and linguistically distinct contrast provided by families of Mexican descent in Southern California (8, 21, 64, 66).

The goals of our study were 1) to examine the cross-cultural validity of expressed emotion among families of Mexican descent, 2) to conduct a replication study of the relation of expressed emotion to schizophrenic outcome, and 3) to examine expressed emotion in relation to family conceptions of the nature and etiology of schizophrenic illness (e.g., *nervios* caused by improper blood circulation) (66). The majority of the immigrant families studied were relatively unacculturated monolingual Spanish-speakers of lower socioeconomic status who identified themselves as *Mexicanos.* The study of expressed emotion among these subjects holds special relevance because the family is typically described as central to the Mexican and Mexican-American sense of self, identity, and well-being (67, 68).

Procedures for the recruitment of patients, the principal methods, sample characteristics, outcome findings, and Spanish-language adaptation of the Camberwell Family Interview have been summarized elsewhere (8). The cross-cultural use of expressed emotion rating scales requires adaptation of the underlying principles of the expressed emotion index and is essential to a culturally meaningful study. To enhance the validity of these scales in the Mexican-descent study, a pilot project was conducted to adapt them in the light of these families' particular cultural context.

The operational definition of criticism was "verbal behavior that is observed through tone of voice or content of speech which clearly conveys dislike, resentment, or disapproval." In the Spanish language, both content and vocal characteristics of speech may communicate criticism, and this approach was therefore deemed linguistically appropriate. The rating criteria for the expressed emotion scales, case studies, and the adaptation of the scales for the Mexican-descent study have been more fully summarized elsewhere (4; unpublished 1978 manuscript of G. Brown et al.).

Although we found that the scale for criticism could be applied with relative facility, the scale for emotional overinvolvement required more adaptation. The basic attitudinal, behavioral, and affective domains measured by the emotional overinvolvement scale were retained for rating purposes, but the content of each of these domains was redefined in the light of the values and norms of the Mexican-descent subjects. It was ethnographically determined that cultural guidelines for kin involvement with an ill relative could be identified and that the families themselves recognized instances when cultural boundaries were surpassed. Indigenous recognition of particular attitudes and behaviors as unusual is crucial to the cross-cultural validity of the concept. For example, among the minority of Mexican-descent relatives with high scores on the emotional overinvolvement scale, several relevant features emerged. These included reports of suffering in relation to *nervios* (an indigenously defined category for distress) and cessation of a family orientation in favor of a relatively exclusive dyadic relationship with the patient. For example, a Mexican mother who stops interacting with all other family members and has suicidal wishes and an extreme problem of *nervios* in relation to the schizophrenic illness of her child is behaving in a culturally unusual manner. (Only 11 [11%] of 109 Mexican-descent relatives were rated high on emotional involvement.) Other family members of the relative with a high emotional overinvolvement score would sometimes describe that person as having "lost it" or going "too far." Also important is the fact that such behaviors were not considered culturally praiseworthy. The matter of cultural definition is crucial to the problem of validity. Behavior reflecting high levels of emotional overinvolvement are culturally unusual, even in the face of serious or long-term family illness.

As found in the British and Anglo-American studies, expressed emotion was significantly associated with the course of schizophrenic illness for patients who experienced some degree of symptomatic recovery following hospitalization for an acute psychotic episode. The study also found a significantly lower rate of high levels of expressed emotion among Mexican-descent relatives than among their Anglo-American counterparts. Our group reported that "this documentation of variations in expressed emotion profiles across distinctive cultural contexts provides support for the IPSS WHO hypothesis that intrafamilial behaviors may account for different prognoses for schizophrenic outcome in different cultural settings" (8, p. 151).

### *Indian Expressed Emotion: The Chandigarh Study*

Like the Mexican-descent study, the Chandigarh study was concerned with the transfer of the expressed emotion rating scales to culturally distinct settings and with the observation of variations in the outcome of schizophrenic patients (33, 39, 40). The Chandigarh study found that relatively few (23%) of the Indian households were classed as high in expressed emotion and that none of the relatives had scores on the emotional overinvolvement factor that were considered high in previous studies (33). Also unlike previous studies, the only expressed emotion factor found to be significantly related to outcome of schizophrenic patients was hostility. These results suggest substantial cross-cultural differences not only in the degrees and types of expressed emotion observed for the Chandigarh subjects but also in the particular factor or factors that may mediate outcome in schizophrenia.

Wig et al. have considered methodological factors that bear on their results. These primarily concern issues of interrater reliability. The assessment of the reliability of hostility—the only predictive expressed emotion factor in their study—was difficult to obtain because it was observed so infrequently. Wig et al. (39) reported that because of this they could not be certain about the transferability of ratings of hostility. However, they concluded that "the findings suggest that this assessment is also likely to be transferable across the linguistic frontiers without significant distortion" (p. 158). For emotional overinvolvement, they reported that one rater's tendency to underrate on this scale led to ambiguities. This difficulty, they asserted, was due to technical training problems rather than the cultural validity and adaptation of these scales as used in the Indian context.

In the light of the need to culturally adapt the rating scales for use in the Mexican-descent study (24), it seems that cultural issues would necessarily be of relevance to an adequate understanding of emotional overinvolvement scores for Indian relatives. The cultural validity of the protocol and rating scales must be established for a meaningful cross-cultural extension of these ratings. Although Wig et al. discussed problems of reliability, the cultural validity of the expressed emotion ratings should also be elaborated. Cultural issues—in terms of normative baselines, rules for familial display of affect, and culturally specific meanings—certainly are important and require careful consideration in the rating process and transfer of the expressed emotion method to Indian culture. The finding that only hostility predicted outcome might signal the necessity of substantial cultural adaptation and interpretation of these scales in the Indian setting. With respect to the negative finding for higher levels of emotional overinvolvement, it may well be that these are virtually absent in the Indian context. It might also be, however, that the findings are related to methodological difficulties related to the cultural validity and adaptation of this scale in Hindi among the Chandigarh relatives. To the limited degree that emotional overinvolvement is present at all, it would undoubtedly be expressed differently in Hindu families than it is in British families.

Another cultural issue raised by the Chandigarh study is interpretation of the finding that expressed emotion profiles among the Chandigarh relatives were surprisingly low or absent and that only hostility was associated with clinical course of illness (40). The finding for hostility is unique. Although the profiles indicative of low expressed emotion in India may substantially account for the good prognosis observed for schizophrenia, it is possible that some other yet unidentified set of sociocultural factors might also account for these results. Another variable in interpreting these results is a clinical factor: unlike the subjects in the other expressed emotion studies, patients in Chandigarh were recruited at the time of their first contact with psychiatric services. Better prognosis is common for first-admission patients.

## EXPRESSED EMOTION PROFILES IN CROSS-CULTURAL CONTEXT

Comparison of expressed emotion profiles shows that Indian families scored lowest (23%), followed by the Mexican-descent (41%), British (48%), and Anglo-American (67%) households (5–8, 33). The Indian households were strikingly lower than all others, and our group reported statistically significant differences between Mexican-descent and Anglo-American families (Yates-corrected $\chi^2=7.92$, df=1, $p<0.01$) and between British and Anglo-American families (Yates-corrected $\chi^2=5.84$, df=1, $p<0.02$) (8). The impressive range and significant differences in these expressed emotion profiles make it evident that it is only in cross-cultural perspective that the critical questions come to light: Why are the Indian scores so low? What about the statistically nonsignificant differences between the British and Mexican-descent households? Is it reasonable to conclude, as certainly no British or Mexican-descent relative ever would, that there are no cultural differences in familial emotional climate of their households? How is it that Mexican-descent and Anglo-American families in the same geographic locale (Southern California) differ so significantly? Why do English-speaking Anglo-American households score significantly higher than their British counterparts?

In considering this latter question, Leff and Vaughn (62) commented only that the differences between London and Los Angeles relatives were "interesting, though not unexpected" (p. 184). Completely unelaborated is the pressing issue of how and why these striking differences might be interesting or expected. Curiously, cultural evidence and hypotheses that could account for differences in expressed emotion profiles are unexamined. Leff and Vaughn argued only that it is important to consider noncultural factors, such as number of hospital admissions and social class. They concluded that neither of these factors proved informative for the observed differences.

Another factor considered by Leff and Vaughn is the historical epoch of each of these studies. This is potentially relevant because the American work was conducted in the 1980s and the British research in the 1960s and 1970s. However, the authors did not define the concept of historical epoch, nor did they discuss how or why expressed emotion might have changed historically. Although in our view two decades is far too abbreviated a historical period for major cultural changes in socialization of affect to occur within family settings, this remains a relevant topic for investigation. Another domain, that of fluctuations in the political economy in the West, could also partially mediate attitudes toward deviance in general and mental disorder in particular (69).

A related factor of importance to an understanding of expressed emotion is social class. Drawing on data from the Mexican-descent study, our group conducted an analysis designed to determine the relative influence of ethnicity and social class variables on expressed emotion (21). We compared a matched Anglo-American subgroup incorporating all lower socioeconomic status families available in the study of Vaughn et al. (7) with the first 30 patients entered into the Mexican-descent study. Comparison of subgroups was necessary because the Anglo-American study group included a full range of social class levels but the Mexican-descent study group included only the lower socioeconomic levels. With social class held constant, an even more striking difference was observed between these two ethnic groups: 83% of the Anglo-American patients, compared with only 43% of their Mexican-descent counterparts, resided in households rated high in expressed emotion ($p<0.003$, Fisher's exact test). These results revealed that, in addition to a strong main effect for ethnicity, levels of expressed emotion are also independently related to socioeconomic status among Anglo-Americans.

The percentage of households with high levels of expressed emotion in the lower-status Anglo-American subgroup was higher than that in the entire Anglo-American study group of 69 families (83% versus 67%). Analysis of variance and covariance revealed that these differences in expressed emotion were not significantly related to patient characteristics (e.g., age, gender, number of hospitalizations, premorbid functioning), relatives' characteristics, or type of household (parental, marital, sibling). The results of the comparison of Anglo-American and Mexican-descent households matched in socioeconomic status provide strong evidence for major differences in cultural styles of emotional response to schizophrenic illness within the family (6). They also provide evidence for the importance of taking into account intracultural variations in expressed emotion, as evidenced through indexes of social class (21).

In addition to overall differences in expressed emotion profiles, the British, Anglo-American, and Mexican-descent studies also reported significant differences in the distribution and mean scores for criticism, hostility, and emotional overinvolvement. For criticism, a low mean score of 1.8 critical comments was obtained for the Indian sample, compared with 3.3 for the Mexican-descent relatives, 6.9 for the Anglo-American relatives, and 7.5 for the British relatives (8, 62). The cross-cultural differences in the mean scores and reported distributions for critical comments, which ranged from 0 to 61, suggest not only cultural variations in family tolerance of schizophrenic illness but also differences in the upper and lower thresholds of criticism observable within these familial environments (62).

Considerably less quantitative variability has been found on measures of emotional overinvolvement and hostility. Perhaps the most notable cross-cultural finding with respect to emotional overinvolvement is the relatively small number of relatives who were rated high on this factor. None of the Indian relatives, 11% of the Mexican-descent relatives, 15% of the Anglo-American relatives, and 21% of the British relatives had scores on this item that were considered high. These results are important because, as already noted, they do not provide cross-cultural support for the idea that families of patients with schizophrenia are appropriately characterized as disturbed or pathological in their interpersonal relations. Indeed, for the Indian relatives the entire concept of emotional overinvolvement appears to be of highly limited relevance. The Mexican-descent data, along with data from other investigations, provide evidence that counters clinical and ethnographic stereotypes in the literature characterizing Latin American women as overprotective and self-sacrificing (8, 70). Results for ratings of hostility reveal that only 16% of Indian, 18% of English, and 13% of Mexican-descent relatives were found to be hostile. The higher figure of 28% reported for Anglo-Americans parallels the relatively higher degree of criticism displayed by those family members (62).

These results demonstrate relatively minor quantitative differences in the levels of emotional overinvolvement and hostility but do not address possible differences in content and qualitative features of these factors. This important topic deserves close attention and has been addressed to some extent in the context of individual studies (4, 21, 61, 62). We turn our attention now to consideration of what sorts of qualitative features might be implicated and their meaning for the theoretical grounding of the construct of expressed emotion.

## AN ANTHROPOLOGICAL ANALYSIS OF THE EXPRESSED EMOTION CONSTRUCT: DIFFERENCES IN LEVELS OF *WHAT*?

In George Brown's excellent 1985 essay on the discovery of expressed emotion (3), he related that upon commencement of his second study of expressed emotion, he knew that something about family life was important to the course of illness but not what. Brown and his associates developed an array of measures of family factors that included not only criticism, hostility, and emotional overinvolvement but also warmth, positive remarks, dissatisfaction, tension, irritability, and (for marital situations) the quality of marital relations (unpublished 1978 manuscript of G. Brown et al.). Only subsequent empirical research served to specify which expressed emotion components were associated with clinical relapse. In discussing the differences between a causal model (that which relates measures in terms of causal links) and a theory (that which explicates what the measure represents), Brown (3) noted that "just *what* is involved cannot be known unless it is clear what the measure represents theoretically. It is inevitable that model and theory will not keep step, and progress in science can be said to come from the struggle to close the gap between them" (p. 21; emphasis added).

In our view, the unknown and theoretically overarching something or somethings indexed by the global construct of expressed emotion are culturally constituted features of kin response to an ill relative. Culture, as a system of shared meanings and symbols, offers the most powerful explanation for observed variations in expressed emotion in different populations. The culturally constituted features—attitudes, affects, and behavior on the part of family members toward their ill relative—are what is being indexed through measurement of expressed emotion. A theoretical accounting of what is inside the "black box" called expressed emotion must therefore prominently concern the concept of culture.

Other theoretical accounts are also necessary. Relatives' responses to a family member's illness include a complex of features that dynamically interact with one another. An abbreviated outline of some of these factors follows.

## FEATURES OF EXPRESSED EMOTION

1. *Cultural interpretations of the nature of the problem.* Relatives' interpretations of the problem are their views of its nature, cause, and course (e.g., laziness caused by illicit drug use that would improve if the patient exercised willpower). These interpretations mediate relatives' emotional responses to the problem (64, 66). The works of Edgerton (71) and Kleinman (72) serve as anthropological classics on this topic.

2. *Cultural meanings of kin relations.* Relatives' responses to an ill family member are formulated in the context of culturally prescribed definitions of family life that suggest appropriate patterns for interpersonal relations among kin. Family relations have sometimes been characterized on a continuum between an individualistic orientation and a family orientation (73).

3. *Identification of cultural rule violations.* Cultures define what counts as behavior deserving of legitimate criticism. Identification of cultural rule violations (e.g., failure to be independent) varies in relation to the values, norms, and expectations in particular settings and in accord with culturally defined statuses that may legitimately exempt individuals from criticism (74).

4. *Vocabularies of emotion.* Cultures differentially construct a universe of discourse on emotion, or ethos, within which the relatives' responses to illness are articulated. Emotions that are culturally salient (e.g., sadness as opposed to anger) provide models that may shape how individuals might or should feel in a given situation (22, 75).

5. *Relatives' personality traits or predispositions.* Although the subject has yet to be explored, variations in individual personality or temperament are common partial explanations for why relatives might display varying degrees of expressed emotion (49). Responses indicative of high levels of expressed emotion may also be partially explained by some degree of shared (and possibly genetic) vulnerability to pathology for relatives and patients alike (76). Variations in relatives' attributional styles have also been explored (14).

6. *Degrees and kinds of patients' psychopathology.* It is frequently hypothesized that variations in degrees of patients' psychopathology might account for differences in relatives' expressed emotion. This assumption undoubtedly holds merit in some instances (e.g., extremely bizarre schizophrenic behavior); however, empirical examination has repeatedly demonstrated a nonsignificant relationship between severity of patients' symptoms and relatives' expressed emotion (5–8).

7. *Family interaction dynamics.* Typical family patterns of identification, communication, and separation can also be expected to shape relatives' emotional responses to an ill family member. Displacement of hostility, ridicule, protection, and devotion, for example, may vary in accord with individual family dynamics. In addition, the socialization of particular family dynamics may be culturally mediated. In a study of schizophrenia in rural Ireland, Scheper-Hughes (77) found that the youngest sons were often expected to preserve the family's identity and longevity. Failure to do so typically generated critical and hostile reactions.

8. *Attempts to socially control a deviant relative.* Expressed emotion can be considered a behavioral intervention strategy of families that is designed to restrict the objectionable activities and actions of a deviant family member (63).

9. *Availability and quality of social supports.* The compositional features of households, including size and kin type, may influence a relative's expressed emotion. For example, expressed emotion may be higher among parents than spouses (8). In an Australian study (41), expressed emotion more successfully predicted relapse in single-parent households than in two-parent homes. Social supports, like life events, might mediate the impact of expressed emotion (62).

10. *Historical and political economic factors.* It has been suggested that explanations for differences in expressed emotion profiles may change over time (62). Changing social and economic conditions may influence the emotional climate of a society in general, with repercussions for how families reflect societal attitudes toward individuals identified as deviant (69). There is also evidence for differences in expressed emotion in relation to social class (21).

We will focus on the first four of these features because the emphasis of this paper is on the cultural basis of the construct of expressed emotion and because these factors have been neglected.

### *Cultural Interpretations of the Problem*

Cultural conceptions of mental disorder—indigenous notions of the nature, cause, and course of illness—have long been a focus of anthropological investigation (64, 66, 71, 72). To what extent do cultural conceptions of the illness mediate expressed emotion in families? Can such conceptions create a culturally legitimate status that inhibits high levels of criticism? Is the cultural locus of the problem deemed to be a personality problem, an illness entity, or an external malevolent agency? Several authors (14, 61) have identified this issue as important to the formation of expressed emotion attitudes. The identification of this factor as a specifically cultural issue in psychiatric research has been slow in coming, however.

In our study of the Mexican-descent relatives (64, 66), the concept of *nervios* served as a cultural label for schizophrenic illness. The term *nervios* is in broad cultural use for a wide range of everyday distress (e.g., tension) and severe illness conditions (e.g., schizophrenia, depression). This inclusive use of the term serves to destigmatize such conditions. Since severe cases of *nervios* are not considered blameworthy or under an individual's control, the person who suffers its effects is deserving of sympathy, support, and special treatment. Moreover, severe cases of *nervios* are potentially curable. It is interesting to note that Mexican-descent relatives do not adopt another possible cultural label for craziness, *loco.* As a *loco,* the individual would be much more severely stigmatized and considered to be out of control with little chance for recovery.

Although such conceptions may be important, other forms of cultural knowledge may also mediate attitudes toward the illness. For example, even Anglo-Americans who believe the problem to be a psychiatric condition called schizophrenia may nonetheless simultaneously believe that their relative is lazy (a culturally based personality attribution), and this might inhibit any possible recovery. That family views often combine broader cultural knowledge with more specific medical explanations points to the fact that these interpretations are complex and sometimes resilient in the face of attempts to modify them through psychoeducational programs offered by psychiatric professionals or advocacy groups (8). Estroff (78) has noted that schizophrenia is typically conceived of as an "I am" disease as opposed to an "I have" illness. The fact that Mexican-descent relatives conceive of schizophrenia as *nervios,* a legitimate illness that is outside the realm of personal control, may have a more salutary impact on personal identity that mediates the course and outcome of illness (21).

### *Cultural Meanings of Kin Relations*

Cultural meanings of family relations may differ along a continuum between a family orientation and an individualistic orientation. In cultures at one end of the continuum individuals may see themselves primarily as members of a larger kin-based social unit, behaving in ways that appear to maximize the family welfare relative to that of the individual. In cultures at the other end, individuals may consider family bonds secondary to the pursuit of their own personal goals and actions. Shweder and Bourne (79) conceptualized such differences in terms of sociocentric as opposed to egocentric definitions of the person. The sense of self in relation to others is important in family settings in outlining cultural preferences for affective and symbolic distancing. Although these formulations must be considered as ideal types, they nonetheless are important to determining different degrees of identification, involvement, and obligation that could in turn affect responses to a relative's illness.

In a study of schizophrenia in Ireland, Scheper-Hughes (77) found that patients were often harshly rejected and extruded from family settings. Ostracism by the family served to delimit the boundaries between self and others by condemning what was considered unacceptably deviant. The criticism and rejection also served to preserve the family identity as morally upstanding. Anglo-American relatives may more sharply delimit boundaries between the normal and the sick family members. For example, some Anglo-American relatives said that they had no personal experience or knowledge of their relative's problem and therefore could not "relate to" or identify with the relative (64). Behaviorally, this sometimes means that relatives feel quite uncomfortable spending much time together. Symbolically, the problem relative comes to be identified as unknown, foreign, and "other." This contrasts sharply with the family processes of identification among Mexican-descent relatives. Defining the problem as *nervios,* a common condition that in its milder forms afflicts nearly everyone, provides them a way of identifying with and minimizing the problem by claiming that the ill relative is "just like me, only more so" (66).

### *Identification of Cultural Rule Violations*

The behavior of individuals with schizophrenic illness can violate a host of cultural norms and proscriptions. This is perhaps why in some societies, such as those of the Javanese or the Pintupi aborigines of Australia, the same term is used for the mentally ill and for young children, indicating that such persons are not fully socialized (22, 75). Edgerton (74) has observed that although societies may allow for acceptable diversity in some human conduct, one knows "when the limits of acceptable variation have been exceeded because the result is 'trouble' in the form of complaints, disputes, accusations, recriminations, and the like" (p. 466). Critical comments may be viewed in this way—as complaints about the perceived violation of rules that people with schizophrenic illness may engage in with disquieting regularity. Shweder (80) underscored Freud's identification of "criticism (and related activities such as accusing and accounting) as the primary activity associated with rules." The criticism component of the expressed emotion research—which empirically makes up the lion's share of the construct—is valid for cross-cultural research if it is grounded in a generalizable definition of criticism as a negative response to cultural rule violations.

A limitation of previous analyses of critical comments is that researchers have considered that only two coding categories—symptom behaviors and enduring personality traits—can adequately inform a qualitative understanding of the nature of critical remarks. This analysis differs markedly from that developed for Mexican-descent and Anglo-American relatives, in which several additional coding categories became essential, and provides an example of the limitations of expressed emotion research in the absence of concern for indigenous perspectives (21). It is also reflective of North American ethnopsychology, since in the British and Anglo-American analysis (62), relatives' preoccupation with personality reflects the broader cultural and ethnopsychological concern about the importance of individual character traits. This analysis is not useful in the case of the Mexican-descent (and we would suspect Indian) relatives, where criticism of relatives on the grounds of personality defects is likely to be a less frequent occurrence.

This point serves to underscore how, in the absence of cross-cultural comparative analysis, science risks reification of our own cultural categories (54). In analyzing the content of critical comments, do we code the data from the perspective of the relatives who are motivated to make the critical comments or from the perspective of the analyst who codes it? The anthropological concern for the importance of perspective (the emic or indigenous categorization of meanings versus the etic or outside analyst's view) is crucial to the identification and interpretation of critical comments. This has yet to receive adequate attention, but we suggest that analysis of critical comments as complaints about cultural rule violations may provide a more productive basis for cross-cultural comparative analyses (4).

### *Vocabularies of Emotion*

Although mental disorder within the family may universally engender painful feelings among close kin, substantial differences exist with respect to the nature, intensity, and meaning of these affects. Relatives necessarily draw upon implicit cultural knowledge of which affects should be expressed and under which conditions they should be inhibited (17–20). Sanctions for and against the expression of certain emotions (such as anger manifest in criticism and hostility) exist as part of the culture's vocabulary of emotion (75). Whereas some societies (such as those of Tahitians or Inuit Eskimos) nearly always censure the expression of anger, others, such as that of the Kaluli of New Guinea, may require such expressions in particular settings (23, 81, 82). Cross-cultural variations in the vocabulary of emotion must play a part in the observed variations in expressed emotion profiles, as recorded for the British, Anglo-American, Mexican-American, and Indian studies.

## SUMMARY AND CONCLUSIONS

Attempts to conceptualize expressed emotion have thus far been largely restricted to a relatively microanalytic view of the characteristics of patients and relatives or their interactional qualities. These conceptualizations are based on personality, attributional, psychopathology, or social control factors. We argue here that these provide only partial understandings of expressed emotion and are primarily useful for intracultural analyses differentiating low and high profiles of expressed emotion. Such explanations do not shed sufficient light on the broader theoretical task of specifying the essential nature of the expressed emotion construct. Comparative research is essential for the theoretical grounding of this construct.

We think the general cross-cultural utility of the component elements of the expressed emotion index should be considered in ways similar to any other research construct, including schizophrenia and depression. These research and clinical constructs may be productively used in comparative research but should always be subject to cross-cultural scrutiny. They cannot be assumed to apply universally, but they may be usefully examined as a starting point. Substantial variation in expressed emotion profiles in different cultures and among different social classes is evidence against assumptions of a universally shared, psychobiologically given human response to schizophrenic illness. Instead, variation in expressed emotion profiles is more properly understood within the context of psychocultural and social variation in relatives' responses to a family member who suffers from schizophrenia. This variation is not limitless, however, and there may well be some features of response that are widely shared around the world.

We argue that the nature of expressed emotion (in the form of verbal criticism and emotional overinvolvement) is clearly grounded in cultural conventions; that is, it is culture specific. However, the cross-cultural presence of expressed emotion factors (criticism and emotional overinvolvement) is a matter for empirical investigation. Therefore, we must disagree with those who suggest that expressed emotion is necessarily ethnocentric or culture-bound. Some careful distinctions must be drawn here. Expressed emotion consists of two principal factors: critical comments and emotional overinvolvement. Without a doubt, the nature and meaning of criticism and emotional overinvolvement are culturally specific. However, it is not correct to assert that these basic elements of family interaction—criticism and emotional overinvolvement—are ethnocentric. They have definitively been found—in culturally specific ways—in the British, Mexican, and Anglo-American contexts, for example. It is our view that the main dimension of expressed emotion—verbal criticism—is likely to be found in some form and frequency in most of the world's cultures.

Yet another reason for focusing on the cross-cultural variations in expressed emotion profiles is the importance of addressing the concern of some family advocacy groups that the expressed emotion paradigm, rather than generating scientific knowledge, presumes that there are deficiencies in individual personalities and families. Even though this perception is in some cases apparently based on misunderstanding, individuals nonetheless feel blamed and responsible for their attitudes or actions (83). Expressed emotion, understood in cross-cultural perspective, can contribute toward a reflective understanding based less on an assumption of autonomous sentiments and actions and more on a constellation of shared features (19, 84).

Quite striking from a cross-cultural psychiatric point of view is the neglect on the part of expressed emotion researchers in calling for a systematic examination of the relationship between culture and expressed emotion. Since the anthropological and cross-cultural psychiatric literature of the past several decades has documented substantial cultural differences in conceptions of psychosis, display of emotion, behavioral rules and norms, and family structure and identification, it is reasonable to expect that features such as these are of key relevance to the explication of expressed emotion. In our view, it is these features that go to the very heart of what the construct of expressed emotion embraces.

# Are Schizophrenia and Affective Disorder Related? A Selective Literature Review

Michael Alan Taylor, M.D.

*Objective: Although most modern investigators accept the Kraepelinian view that schizophrenia and affective disorder are biologically distinct, others have suggested the psychoses are on a continuum of liability. This article is a selective review of evidence for the continuum model. Method: The author focuses on family, twin, and adoption data that do not support the Kraepelinian view of psychosis. Evidence characterized to a lesser extent includes the frequency of intermediate forms of illness (i.e., schizoaffective disorder), the inability to separate psychoses by classical symptoms into well-defined clusters, and the inability of laboratory measures to clearly define psychotic subgroups. Results: The data demonstrate that schizophrenia and affective disorder do co-occur in some families. Whether this co-occurrence reflects true overlap is unclear, and significant pathophysiological heterogeneity may underlie clinical continuity. In some recent studies the inclusion of nonmelancholic depressions in the affective illness category may have masked overlap. Conclusions: The author suggests that the Kraepelinian view of psychoses may need modification. Future research should focus on factors that may reveal overlap between schizophrenia and affective disorder: severity of schizophrenia and affective disorder in probands, severity of depression in relatives, the effect of the unipolar-bipolar disorder relationship on the co-occurrence of affective disorder and schizophrenia, and the relationship of nongenetic factors that might alter the clinical expression of a shared genotype. Also, investigators should not presume a dichotomy or continuum but should examine pure and mixed pedigrees and look for state- and trait-related endophenotypes, the convergence of which would provide the basis for focused molecular genetic study.*

(Am J Psychiatry 1992; 149:22–32)

> It is becoming increasingly clear that we cannot distinguish satisfactorily between these two illnesses and this brings home the suspicion that our formulation of the problem may be incorrect.
>
> —Kraepelin (1)

Most investigators and theorists studying schizophrenia accept the premise that schizophrenia is biologically distinct from affective disorder. The most compelling evidence supporting this Kraepelinian view of psychosis derives from family and twin data (2–4) that are interpreted as demonstrating little, if any, shared liability between the two major psychoses.

Despite this consensus, several theorists have proposed that schizophrenia and affective disorder are not distinct conditions but are, in fact, opposite ends of a continuum on which schizophrenia is the severest form and schizoaffective disorder is intermediate (5). Others have suggested a third alternative, that schizophrenia and bipolar affective disorder are two independent conditions and that unipolar and schizoaffective disorders are expressed in the relatives of patients in both categories (6). Evidence supporting these views also primarily derives from family and twin data, but it is considered weak or representative of idiosyncratic study groups, methods, or both.

The number and variety of studies which support the Kraepelinian view of psychosis exceed those which do not. A thorough review of that literature is not practical here. However, a detailed review of the data that suggest the accepted nosologic dichotomy may need to be modified has not been done, and such an exercise would be instructive. Nevertheless, critically reviewing the methodological shortcomings of these and pro-Kraepelinian studies is also beyond the scope of a journal article. Therefore, it is important to recognize that

before 1980 no published family study met the criteria required of any modern study: prospective proband and relative selection, personal interviews, systematic data collection instruments, structured diagnostic criteria, and independent, blind diagnosis of probands and relatives. Most twin and adoption studies have similar problems. These deficiencies have been reviewed elsewhere (2, 7) and will be highlighted here only for illustration. Despite these problems, however, the literature is remarkably consistent in providing evidence that schizophrenia defined by most criteria is familial, that affective disorder is familial, and that in a significant minority of families the two psychoses co-occur.

## FAMILY STUDIES

### *Affective Disorder in Relatives of Schizophrenic Probands*

Rüdin (8), who worked with Kraepelin and who clearly accepted the dichotomous view of psychosis, presented family data in calculating the risk of a sibling's developing classical schizophrenia if another family member was mentally ill. Although the risk for schizophrenia was high (6.2%) if the ill relative was schizophrenic, it was higher if the ill relative had a nonschizophrenic (most often affective) psychosis (8.2%) or alcoholism (7.8%). If alcoholism and a nonschizophrenic psychosis were both present, then the risk for schizophrenia in other relatives was 22.7%. Further, although a sibling's risk for developing schizophrenia was high if the ill sibling was schizophrenic (6.2%), the risk for developing a nonschizophrenic psychosis was even higher (10.3%). Indeed, Rüdin found almost equal numbers of relatives with affective disorder and relatives with schizophrenia in the families of his schizophrenic probands.

Odegaard (9) gathered congruent data from Norway by using the family history method to assess relatives (N=824) but personally interviewing probands, making a final diagnosis only after at least a 5-year follow-up. Of 109 psychotic relatives of his "severe defect" schizophrenic probands, 78% were schizophrenic and about 15% were affectively ill. The disorders of another 7% were labeled "reactive psychosis," a popular concept in Scandinavia that McCabe (10) demonstrated has a familial relationship to affective disorder. Although appropriate population base rates are not available for comparison, nearly one-quarter of the psychotic relatives of Odegaard's schizophrenic probands could be considered affectively ill. Further, among the psychotic relatives of Odegaard's manic-depressive probands, 19% were diagnosed as schizophrenic (well above any known base rate), indicating the co-occurrence ran in both directions.

Penrose (11) studied all known families in which two or more members entered one of the Ontario mental hospitals during an 18-year period (5,456 affected pairs). He reported that, although schizophrenia and affective psychosis remained true to type in most families, "schizophrenia and affective psychosis are not very distinct entities and groups of closely related familial cases include both diagnoses." For example, of 184 subjects who each had at least one schizophrenic parent, 34 were diagnosed as having an affective disorder, whereas of 437 subjects who each had at least one manic-depressive parent, 205 were diagnosed as schizophrenic. Penrose's methods and diagnostic procedures, however, would not meet modern standards. Nevertheless, Karlsson (12) also observed both illnesses among the siblings of Icelandic and Californian schizophrenic probands, Reed and Hartley (13) found an excess of schizophrenia among all first-degree relatives of affectively ill U.S. probands, and Powell et al. (14) reported that manic-depressive Scottish parents had both manic-depressive and schizophrenic children, in the ratio of 3:2.

More recent family data are also inconsistent with the Kraepelinian dichotomy. For example, in their "Iowa 500" study, Tsuang et al. (15) concluded that their data "support the distinction between schizophrenia and affective disorders, although the distinction between schizophrenia and mania was not clear." The morbid risks for bipolar affective disorder in the first-degree relatives (personal and approximate interviews) of schizophrenic, manic, and depressed probands were 2.4%, 5.3%, and 3.0%, respectively, whereas the morbid risk for bipolar disorder in the first-degree relatives of comparison subjects was only 0.3%. Abrams and Taylor (7) also reported an excess of affective illness (6.9%) in the first-degree relatives of schizophrenic probands, but they included no group of subjects for direct comparison. Tsuang et al. also concluded that their data refuted the bipolar-unipolar affective disorder subtyping, and Taylor et al. (16, 17) also presented their own data and data from the literature questioning the unipolar-bipolar dichotomy. Logic suggests that if bipolar and unipolar disorders are, indeed, variations of the same process and that mania and schizophrenia are related in some way, then the clear Kraepelinian dichotomy is no longer tenable.

Similarly, Kendler et al. (4), reanalyzing the Iowa 500 data, reported that, compared to the relatives of comparison probands, the relatives of schizophrenic probands had a significantly higher risk for schizoaffective disorder (1.4%) and a difference in risk for bipolar disorder (1.2%) that approached statistical significance. Mendlewicz et al. (18) also reported a high risk for bipolar affective disorder (8.6%) in the first-degree relatives of schizophrenic probands, and Guze et al. (3), in an outpatient study, reported a questionable excess of primary depressive disorder (8.1%) in the first-degree relatives of schizophrenic probands than in the relatives of psychiatric comparison subjects (5.7%).

A number of studies, however, have not shown an increased risk for affective disorder among relatives of schizophrenic probands (19, 20) (see discussion that follows). In one such study, Coryell and Zimmerman (21) also failed to find a high prevalence of schizophrenia among relatives of any patient group when compared to relatives of normal subjects. Closer inspection of their data, however, reveals that of the six families of schizophrenic probands that had secondary cases of any major mental disorder, the secondary diagnoses were only affective disorders in three families and affective disorder and schizotypal personality disorder in a fourth family.

### *Schizophrenia in Relatives of Affectively Ill Probands*

The co-occurrence of schizophrenia and affective disorder also has been observed in families of affectively ill probands. For example, Angst et al. (22), in a large family study, also could not find support for the unipolar-bipolar dichotomy in their group of first-degree relatives of unipolar and bipolar probands. In addition, although base rates were not reported, among the first-degree relatives (N=617) of their bipolar probands (N=95), the morbid risks for schizophrenia and for schizoaffective disorder were higher than expected: 1.9% and 1.5%, respectively. The risk for schizophrenia among siblings was 2.5%, whereas among the probands' children it was 4.8%. In contrast, Loranger (23), who reported family history data for 200 manic probands, did not find a higher than expected risk for schizophrenia. However, in the Loranger study, the relatives' diagnoses were apparently made by persons who were not blind to the probands' diagnoses. In addition, in a large Swiss family study, Scharfetter and Nusperli (24) compared morbid risks for schizophrenia in the first-degree relatives of schizophrenic and affectively ill probands and found them to be 8.9% and 3.3%, respectively. Although relatives of normal subjects were not included for comparison, the risk for schizophrenia in relatives of other normal subjects diagnosed by similar criteria (*ICD-9*) is about 0.6%, suggesting the risk in the relatives of the affectively ill probands in the Scharfetter and Nusperli study is significantly higher than expected. Smeraldi et al. (25) examined the relatives of affectively ill probands in Lombardy and observed a higher than expected risk for Feighner-defined schizophrenia in the siblings of unipolar, but not bipolar, probands. Lastly, in the Iowa 500 study (15), in which the risks for bipolar affective disorder were similar in the relatives of schizophrenic and bipolar probands, the risks for schizophrenia in these relatives were also similar and statistically greater than the risk for schizophrenia in the relatives of normal comparison subjects. The morbid risks for schizophrenia in the relatives of schizophrenic, manic, and normal probands (personal and approximate interviews) were 5.5%, 3.2%, and 0.6%, respectively. The risk for schizophrenia in the relatives of depressed probands was 1.7%.

Nevertheless, failure to find an excess of schizophrenia in the first-degree relatives of manic-depressive patients has been reported many times (4, 26, 27). However, in an extension of one of these studies (4), Kendler et al. (28) did find an excess risk for schizophrenia (4.3%) in the first-degree relatives of probands with "psychotic affective disorder." In fact, the risk for schizophrenia in these families was higher (although not statistically significant) than the risk for schizophrenia in the families of schizophrenic probands (3.7%). The morbid risk for affective disorder in the relatives of these probands was also much higher (20.0%) than base rates, suggesting that severity of proband illness may account for some of the discrepancy among studies assessing the morbid risk for schizophrenia in the relatives of affectively ill probands. Indeed, in a separate analysis (29) of the same data base, the same authors estimated the risk for schizophrenia in the relatives of bipolar patients with psychotic symptoms to be 2.5%, compared to 1.0% in relatives of normal comparison subjects ($p<0.05$). These figures were separate from those for schizoaffective disorder (1.4% versus 0.1% for normal subjects) and atypical psychosis (2.5% versus 0.3% for normal subjects), which were also higher in the relatives of schizophrenic probands. Tsuang et al. (29) stated, "If affective disorder with psychotic symptoms is not included as a subgroup of major affective disorder, then the results, based on familial data, support the rationale behind the nosological distinction between DSM-III schizophrenia and major affective disorders."

However, it seems more reasonable to conclude not that the data should be excluded but, rather, that the nosology should be modified. Tsuang et al. (29) further stated, "It may be possible that some affective disorders with psychotic symptoms could be a genetic variant of schizophrenia." But they then concluded, "Therefore, including all affective disorders with psychotic symptoms in the category of DSM-III major affective disorder may lead to over-diagnosis of affective disorders."

Finally, in a series of studies, Gershon et al. (6, 30) also assessed the risks for affective disorder and for schizophrenia in the first-degree relatives of schizophrenic and affectively ill probands. Relatives of schizoaffective and normal probands were also assessed. In their 1982 study (30), these authors found a familial relationship between schizoaffective and affective disorders, whereas in their 1988 study (6), they found a familial relationship between schizoaffective disorder and schizophrenia. These findings led to their hypothesis that there are two distinct psychoses, schizophrenia and bipolar affective disorder, and that unipolar and schizoaffective disorders are somehow related to both. Crow (5) reviewed these studies and concluded that the data just as strongly suggested a continuum from affective disorder through schizoaffective disorder to schizophrenia. The morbid risks for bipolar and unipolar disorder found by Gershon et al. (6) in the first-degree relatives of schizophrenic probands (2.2% and 14.7%, respectively) were two to three times those of the relatives of normal subjects (0.8% and 6.7%, respectively). Gershon et al. also found that the relatives of chronic psychotic patients who had abused drugs had a morbid risk for unipolar disorder of 18.8%. Coupled with findings of associated birth complications (31, 32) and prenatal viral exposure (33) among schizophrenic patients, these data are consistent with the expression of liability along a continuum from affective disorder through schizoaffective disorder to schizophrenia, depending on the degree of liability and the exposure to various neurologically damaging factors.

## TWIN AND ADOPTION STUDIES

Data from twin and adoption studies have frequently been cited as support for our present nosology (2). Nevertheless, some twin and adoption data do not fit this dichotomous classification. For example, the London twin study by Slater and Shields (34) provides classic evidence for a genetic predisposition to schizophrenia; the concordance rates for monozygotic and dizygotic twins were 65% and 14%, respectively. However, Slater and Shields also found that among the siblings of schizophrenic patients in the index twin pairs the prevalences of affective disorder and schizophrenia were similar and that they had more parents with affective disorder than with schizophrenia (16 versus 12 individuals). Subsequent reports of sets of twins (35, 36) and triplets (37) with schizophrenic and affectively ill individuals also suggest some relationship between the two psychoses, as do reports of pedigrees in which the two illnesses co-occur (38). This co-occurrence is best illustrated by Farmer et al. (35), who applied *DSM-III* criteria to twins from the Maudsley schizophrenic twin series. Farmer et al. studied 24 monozygotic and 33 dizygotic twin pairs in which at least one member was originally diagnosed as schizophrenic and for which the original concordance rates for schizophrenia were 42% and 9%, respectively. Five monozygotic schizophrenic probands were found to have a co-twin with a *DSM-III* affective disorder, and a sixth had a co-twin diagnosed as having either schizoaffective or bipolar II disorder. A seventh index twin, rediagnosed as having schizophreniform disorder (criteria identical to those for schizophrenia except no duration criterion), had a co-twin diagnosed as having depression. Thus, seven of 24 monozygotic twin pairs had one member with a schizophrenic syndrome and the other member with an affective syndrome. Six pairs remained concordant for schizophrenia. Farmer et al. concluded that the problem may lie with the *DSM-III* criteria, but it is equally plausible that these data indicate some shared liability among some subgroups of patients with schizophrenia and affective illness.

Similar problems in deciding whether the data indicate poor diagnostic specificity or shared liability emerge from some of the adoption literature. For example, in the Danish adoption study (39), of 69 biological parents of index schizophrenic adoptees, 10 were considered to have acute schizophrenia (a short, rapidly developing psychosis with intact affect) or schizoaffective disorder; both of these categories are considered, by some investigators, to be variations of affective disorder (40). Eight parents were also diagnosed as borderline, and nine were given doubtful diagnoses of schizophrenia or schizoid personality. Further, among the schizophrenic adoptees, rediagnosis identified only three patients with unequivocal (i.e., chronic) schizophrenia (41). Thus, although adoptees are similar to their biological parents and their biological parents have more illness than do normal comparison subjects, this pattern is best demonstrated for a spectrum of psychotic syndromes, rather than for the classic Kraepelinian dementia praecox.

## OTHER EVIDENCE

In addition to familial studies, problems with the Kraepelinian dichotomy derive from three other areas: 1) intermediate forms, particularly schizoaffective disorder, are common; 2) there is no clear separation of the psychoses by classical symptoms into well-defined clusters; and 3) laboratory measures, while delineating psychotic from nonpsychotic patients, have not clearly defined psychotic subgroups.

First, if the Kraepelinian dichotomy is valid, intermediate forms (usually lumped into the category schizoaffective disorder) should be uncommon. It is difficult, however, to precisely determine the prevalence of this intermediate group because correlations between definitions of schizoaffective disorder are poor (42), making generalizations difficult. Nevertheless, Brockington and Leff (42) found that 8% of hospitalized psychotic patients met three of eight definitions, and Surtees and Sashidharan (43), using the Research Diagnostic Criteria (RDC) to study community samples, found that 5.7% of the adult subjects who received psychiatric diagnoses had schizoaffective disorder, and this rate is similar to that found for schizophrenia. Johnson (44) also reported that one-half of untreated new acute schizophrenic patients and about one-third of chronic schizophrenic patients were depressed. Their depression was defined as "clinically meaningful and likely to provoke some treatment," and they each scored 15 or higher on the Hamilton Rating Scale for Depression. Montgomery (45) reported a similar prevalence of depressive symptoms in schizophrenic patients meeting the criteria of the 1977 NIMH Diagnostic Interview Schedule (DIS) and the Present State Examination.

All current concepts and definitions of schizoaffective disorder combine in some way affective symptoms with other features thought to be associated with schizophrenia (e.g., certain kinds of hallucinations and delusions). Studies of these phenomena, however, clearly demonstrate that these schizophrenic-like features occur with high frequency among patients with affective syndromes (46). For example, first-rank symptoms, used to define schizoaffective disorder in the RDC, appear to occur in 15% to 20% of patients with acute mania, whereas persecutory delusions and auditory hallucinations, used to define schizophrenia and schizoaffective disorder in *DSM-III* and *DSM-III-R*, occur in over one-third of the patients with acute mania (47, pp. 15–55). These figures suggest that somewhere between 25% and 30% of manic patients could, by several standards, be considered to have schizoaffective disorder or a cross-sectional clinical picture intermediate between those of "pure" schizophrenia and affective disorder. Although some (see review, 40) have argued that schizoaffective disorder is simply a more severe form of affective disorder, others have suggested that these patients have either a third type of psychosis (48) or a variation of schizophrenia (49). Still others (50) have concluded that the data do not fully support any of these views, that the label "schizoaffective" simply means diagnostic uncertainty, and that this patient group is heterogeneous. The lack of consensus suggests that the ultimate conclusion about the nature and extent of schizoaffective disorder will to a large degree determine the boundary between schizophrenia and affective disorder. The unclear delineation of schizoaffective states and their considerable prevalence weakens the case for the Kraepelinian dichotomy.

More damaging to the Kraepelinian dichotomy is the work of Kendell and associates (51–53). Kendell and Gourlay (51, 52) tried to discriminate affective disorder from schizophrenia on the basis of various features thought to be characteristic of each disorder. They were unable to do so, finding a unimodal distribution of symptoms, rather than the bimodal distribution required by the Kraepelinian model. Other investigators have also observed this unimodal distribution (54) or have obtained ambiguous results (55, 56). Kendell and Brockington (53) further assessed the putative boundary between affective disorder and schizophrenia by examining the relationship between symptoms and outcome in 232 psychotic patients; the dichotomy predicted a nonlinear relationship. Such a relationship was not apparent.

In contrast with the several studies in which a clear symptom distinction between schizophrenia and affective disorder could not be demonstrated is the study by Cloninger et al. (57), who assessed the putative distinction by a series of discriminant analyses of symptoms observed in a large group of outpatients and their ill relatives. Cloninger et al. found a point of rarity and concluded that their data fit the Kraepelinian model, but they pointed out that because the clinical features used to establish the point of rarity did not include emotional blunting or negative features, their findings might not be applicable to hospitalized or chronic (hebaphrenic) patients.

Last, although the psychoses are associated with abnormalities in brain structure (47, pp. 503–540; 58; 59) and function (47, pp. 416–488, 541–595), none of these abnormalities is pathognomonic, and many are observed in both patients with schizophrenia and patients with affective disorder. For example, the degrees and prevalences of soft neurologic signs (about 70% in each psychosis) (60), structural brain abnormalities (10%–30% in each psychosis) (47, pp. 503–540; 58; 59), and neurotransmitter system aberrations (47, pp. 416–458; 61) in schizophrenia and affective disorder are more similar than dissimilar.

Particularly striking are the data on structural brain abnormalities in psychotic patients. Since the presentation by Johnstone et al. (62) of CT scan findings characterizing some schizophrenic patients as having some (not necessarily clinical) degree of cortical atrophy and ventricular enlargement, the specificity of these findings to schizophrenia has been assumed by some investigators. Thus, much of the brain imaging literature now focuses on whether the schizophrenic patients with CT abnormalities represent the genotype or the phenocopy of schizophrenia. Although a full review of this literature is beyond the scope of this paper, it is clear that the structural brain abnormalities observed in some schizophrenic patients are not specific and are also observed in manic patients and depressed patients.

For example, of the more than 40 studies (58, 59) measuring the lateral ventricle system in schizophrenic patients, over three-fourths demonstrated significantly larger ventricles in these patients (6% to 40% of patients) than in various comparison groups. Larger ventricles did not correlate with greater age (63), suggesting little structural change over time, but did correlate with greater illness severity, social impairment, and cognitive dysfunction. Ventricular enlargement has also been observed in the ill members of monozygotic twin pairs discordant for schizophrenia (64). Other findings in schizophrenic patients include third ventricle enlargement, cortical gyri shrinkage (particularly frontotemporally), cerebellar atrophy (5%–17% of patients) (58, 59), cerebral hemisphere asymmetry, and thickening of the corpus callosum. Although there have been relatively few MRI studies of schizophrenia, and some of those studies have not shown differences between schizophrenic and normal comparison subjects (65), most have shown patients to have smaller frontal lobes and cerebral size and complex density (T1) abnormalities in several brain regions (58, 66, 67). Similar MRI abnormalities have also been reported in the schizophrenic twins in discordant monozygotic pairs (68).

Strikingly similar brain structure abnormalities have also been observed in patients with affective disorder. For example, numerous CT studies of manic patients have shown them to have enlarged lateral ventricles (69, 70), frontotemporal sulcal widening, and cerebellar atrophy (71, 72). As with schizophrenia (58, 59), a few studies did not show these abnormalities (70). As yet, clinical correlates have not been established. Depressed patients, particularly those with psychotic features (73), high cortisol levels (74), and greater severity and poor outcome (75), also have ventricular enlargement and frontotemporal sulcal widening.

Abnormal T1 values shown by MRI scans have also been reported in bipolar patients (76, 77), and these resolved somewhat after treatment with lithium. Ventricular enlargement in some depressed patients has also been reported to resolve with clinical improvement (74), as is the case in some patients with cerebral atrophy secondary to therapeutically or pathologically related hypercortisolism (78). MRI studies have also demonstrated smaller than normal frontal lobes in bipolar patients and elderly depressed patients (58, 59). Bipolar patients have also been found to have abnormally small temporal lobe volumes (79), and depressed patients have been found with

MRI to have small caudate volumes (80). This pattern is particularly similar to the MRI T1 findings in some schizophrenic patients (81).

Although there are significant similarities between the CT/MRI findings in schizophrenia and affective disorder, there is some evidence that the abnormalities in schizophrenia occur early in the course of the illness and do not appreciably change over time, whereas the abnormalities in affective disorder occur later and may fluctuate with the clinical picture. These similarities and differences could result from 1) different pathophysiologies with a common structural pathway or 2) a process resulting from some shared liability that, as with the signs and symptoms of the two syndromes, is expressed differently in schizophrenia and affective disorder. Jeste et al. (82), in an extensive review of this literature, reached similar conclusions and suggested that neuropathological studies (rare in patients with affective disorder) would need to be done to resolve this issue.

Also of interest are the data related to dexamethasone suppression test results for schizophrenic patients. Although it is now felt to be an epiphenomenon without etiologic significance, dexamethasone nonsuppression has been strongly associated with affective disorder, particularly melancholia (i.e., it was reported to have high specificity and sensitivity). However, in his review and meta-analysis of data from this literature, Veragoni (83) found that 26% of schizophrenic patients were nonsuppressors, significantly more than the 5% among normal subjects. Further, Tandon et al. (84) found that 39% of unmedicated patients with RDC/*DSM-III* schizophrenia were nonsuppressors and that nonsuppression was related to negative but not depressive symptoms (as rated with the Scale for Assessment of Negative Symptoms and Hamilton depression scale, respectively). In addition, Altamura et al. (85) studied 54 patients with *DSM-III* schizophrenia divided into positive and negative symptom subtypes and found that 40% overall and 62% of the negative symptom group were nonsuppressors. This last figure is higher than that reported for melancholic patients (50%).

The degree of overlap among studies of biological variables is such that Meltzer (86), reviewing this literature, concluded a continuum was a reasonable interpretation of the data. Consistent with these biological similarities is the fact that, although schizophrenic patients as a group have a worse outcome than do patients with affective disorder, when these two groups are combined with schizoaffective disorder patients the overlap among the three groups is significant and suggests a unimodal distribution (87–89). Also, similar biological treatments (e.g., neuroleptics, ECT, anticonvulsants, lithium [90]) are of benefit to patients in each diagnostic category. Finally, follow-up studies (91, 92) show that, although most patients experience the same form of illness during follow-up periods, some experience early episodes of affective disorder followed by episodes of schizophrenia (about 10%), or vice versa (about 5%). In some earlier studies the diagnostic criteria were poor and the diagnoses of schizophrenia were probably erroneous, but the changes in illness form noted in the more recent studies are not due to changes in diagnostic system, as the same criteria were applied throughout.

## DISCUSSION

This review is selective, i.e., primarily presenting studies which are consistent with the idea that there is a relationship between some forms of schizophrenia and of affective disorder. Nevertheless, on the basis of them it seems justifiable to conclude that data from these family and twin studies and, to a lesser extent, some adoption studies demonstrate that schizophrenia and affective disorder co-occur in some families. However, is this co-occurrence significant, and does it indicate overlap?

Certainly, most investigators have not concluded that there is significant overlap (2). How can that view be reconciled with the findings I have reviewed? First, in some of these "negative" studies (4, 29), co-occurrence was in fact observed but the investigators did not address their findings. In others (93), no mention of co-occurrence was made, and, as at least base rates should have been observed, perhaps the investigators did not look for co-occurrence. In addition, some studies that did not show significant co-occurrence had substantial methodological problems. For example, the study by Pope et al. (94) was based solely on chart information, and Loranger's study (23) was limited by family history information obtained only from charts, lack of a comparison group, relatives' diagnoses that were made by persons who were not blind to proband diagnosis, and diagnoses of only the ill relatives who had received treatment. Nevertheless, in several studies (19, 95) the methods were good and the group sizes were adequate, and no significant co-occurrence was observed. These studies, coupled with those which showed significant co-occurrence, suggest a complex pattern of heterogeneity: some psychoses appear to be on a continuum of liability, whereas other psychoses with similar signs and symptoms have different and distinct etiologies.

For such a complexity of relationships, significant and varied environment-gene interactions are likely. For some patients these interactions would be unique, i.e., if they had a specific genotype independent of the genotypes for other psychoses (see review, 96). For schizophrenic patients and patients with affective disorder who share a genotype, the shared genotype could be for a propensity for psychosis. Environmental factors would largely determine whether the vulnerable individual would be unaffected, affectively ill, schizoaffective, or schizophrenic. Winokur (97) has suggested this model for the affective disorders, but it could apply equally well to a schizophrenia-affective disorder continuum. Environmental factors that have been studied as possible influences on the expression of psychosis include gestational and perinatal CNS damage (31, 32), childhood head trauma (98), prenatal CNS viral infection (33), and drug abuse (99). The size, site, and precise timing of the lesions induced by these environmental factors have differential, important effects on genes (100) and on neuronal cell migration and pruning during development, and they may not be manifested until sexual maturity. Thus, the degree of pathophysiological heterogeneity underlying the psychoses could be extraordinary, even if some forms of psychosis have a common genotype.

Another argument against overlap between schizophrenia and affective disorder derives from studies of dual matings, i.e., cases in which one parent is schizophrenic and the other has affective disorder, or both parents have either schizophrenia or affective illness (2, pp. 89–93). These studies do not indicate that the psychotic offspring of one parent who is schizophrenic and one who is affectively ill have mixed psychoses, as one might expect if the parents' different clinical pictures resulted from similar liabilities, which could be expressed as "pure" or as intermediate forms. In most cases, parents who are both diagnosed as schizophrenic do not have both manic-depressive and schizophrenic offspring. However, dual matings are rare (but patients with mixed symptoms, i.e., schizoaffective disorder, are not), the diagnostic criteria in these studies were poor or nonexistent, and the diagnoses of the offspring were usually not made by persons who were blind to the parents' diagnoses. Further, it has not been demonstrated that schizophrenic and affectively ill patients can be clearly separated by symptoms or biological variables or, when they are combined with patients with schizoaffective disorder, that there is a clear separation of the psychoses by long-term outcome or specificity of treatment response. The removal of patients with schizoaffective disorder from studies designed to demonstrate the separation of schizophrenia from affective disorder may have been justified at one time in the search for the simplest answer to the nature of the psychoses, but this strategy has not been successful and continued exclusion may be artificial and judgmental.

Although schizoaffective disorder constitutes between 10% and 30% of functional psychoses (depending on the criteria one uses), it is unclear how many schizophrenic patients have family histories of affective disorder and how many affective disorder patients have family histories of schizophrenia. In one study that examined the first part of this relationship (92), of 135 patients diagnosed as schizophrenic (most of whom met *DSM-III* criteria), about 20% had family histories of either unipolar (13.3%) or bipolar (7.5%) affective disorder. The diagnosis of these probands, however, was unclear because during a variable follow-up period 70% of those with family histories of bipolar illness, 66% of those with family histories of unipolar disorder, and 40% without any family history of affective disorder had subsequent episodes of affective illness.

It is also unclear what the morbid risks are for schizophrenia and affective disorder in the first-degree relatives of probands with these diagnoses. From my review, it appears that the risk for schizophrenia among the relatives of probands with affective disorder is between 0.5% and 3.5%, whereas the risk for affective disorder in the first-degree relatives of schizophrenic probands is about 6% to 8%.

Are these risks higher than those of the general population and, therefore, suggestive of shared liability? Certainly, the risk for schizophrenia in the first-degree relatives of affective disorder probands is not overly impressive, and most studies have not shown a high risk. Most family studies of affective disorder, however, did not address the risk for schizophrenic disorder in relatives. If some psychoses are on a continuum, the risks in relatives of affective disorder probands might be expected to be only slightly higher than expected for schizophrenia, high for affective disorder, and somewhere in between for schizoaffective disorder. For the relatives of schizophrenic probands, the risk for schizophrenia might be high, but the risks for schizoaffective and affective disorders would also be high. There is some evidence consistent with these expected patterns. For example, although most studies of schizophrenic subjects did not assess intermediate forms of psychosis (i.e., schizoaffective disorder), several studies (4, 21, 27, 29) did so and showed that the risk for schizoaffective disorder was higher than average (about 2%) in the first-degree relatives of schizophrenic probands. Other studies (21, 22, 30) have demonstrated a high risk for schizoaffective disorder (about 2%–3%) in the first-degree relatives of affective disorder probands. There are 14 published family studies of schizoaffective disorder (see reviews: 40, 101, 102) with apparently adequate numbers of probands (more than 40) and adequate methods. Among these, the mean risks in relatives for schizophrenia, schizoaffective disorder, and affective disorder were 3.72%, 5.30%, and 15.68%, respectively.

Whether the risk for affective disorder in the relatives of schizophrenic probands is higher than expected remains unclear and may ultimately be determined by what depressive syndromes are included in the affective disorder category and the resulting conclusion as to the population risk for affective disorder. The present-day practice of including nonmelancholic major depression and dysthymia in the category of affective disorder leads to population risk figures of about 6% (103, 104), although some investigators reported much higher risks (105). However, using the European, narrower view of depression, Slater and Cowie (106) estimated the risk for manic-depressive illness to be closer to 1%. Eastwood et al. (107) reached a similar conclusion on the basis of the prevalence of lithium treatment in metropolitan Toronto. If the lower figure is accurate, then the risks for affective disorder in the first-degree relatives of schizophrenic probands in several studies are clearly higher than expected. Hallstrom's Swedish study of depression (108) used *DSM-III* criteria and showed a population prevalence of 6.9% for all major depression but only 2.9% for melancholia. If depression is heterogeneous, as suggested by several studies (109, 110), then it is important to determine whether it is the melancholic variety that co-occurs in relatives of some schizophrenic probands and whether that prevalence is greater than that of the general population.

It is also important to recognize that much of the present-day information on population risk was derived with controversial methods. For example, many studies (111, 112) used lay interviewers who administered the DIS, a structured interview instrument with only modest reliability and low sensitivity for depression, schizophrenia, and mania (respective kappas=0.63–0.68, 0.51–0.60, 0.63–0.66; sensitivities=71%–80%, 50%–70%, 65%–75%). Independent assessments of the DIS (113) suggest that prevalence estimates based on its use with lay interviewers are significantly different from those based on the standard psychiatric diagnosis and that subjects identified as cases by the two methods often differ. The kappas were also low for major depression (0.25), schizophrenia (0.19), and mania (0.09). Further, estimates of depressive illness in some studies were so high that they call into question the clinical meaningfulness of the behavioral clusters labeled "depression." For example, in a study of children at high risk for depression, Weissman (114) found that among the children of the nondepressed, normal comparison parents, 13.4% had major depression, 14.9% had dysthymia, 13.4% had conduct disorder, and 17.9% had anxiety disorder. Over 50% of the children from *normal* households were identified as psychiatrically ill. All these data suggest that the Kraepelinian view of the psychoses may need to be modified. This dichotomy does not account for data from a number of family and twin studies, nor can it be clearly demonstrated from clinical and laboratory data. Further research in all these areas is essential, and studies should be designed without preconception and include patients with various forms of psychoses. Research should also focus on the factors that may account for differences across studies, e.g., number of subjects, severity of schizophrenia and affective illness in probands, severity of depression in relatives, the effect of the unipolar-bipolar affective disorder relationship on affective disorder in relatives of schizophrenic probands, and nongenetic factors (street drugs, perinatal problems, viral disease) that might alter the clinical expression of a shared genotype.

Continued maintenance of an unmodified Kraepelinian, dichotomous view of psychosis, given the data from the studies reviewed here, requires some speculation. For example, it could be argued that the manipulation of typical cross-sectional and longitudinal clinical information in studies failing to show clear clinical clusters is fruitless, because the two putative diseases differ on clinical dimensions orthogonal to the clinical features usually studied. What these other features might be is unclear. Perhaps it would prove helpful to focus on social, interpersonal, and neuromotor behaviors that have been reported to be odd in some psychiatric patients (115–117) but are not classifiable into traditional psychopathological categories.

Another alternative could be that there are two distinct illnesses but (like some cancers) they share so many of the same cross-sectional and longitudinal clinical features that their distinction can only be observed through laboratory measures. However, present laboratory technology has not provided evidence for this clear distinction of the psychoses. The application of hypothesis-generated laboratory measures to pure and mixed pedigrees to determine state- and trait-related endophenotypes might provide support for this alternative defense of the Kraepelinian dichotomy.

An alternative to the continuum model that is also inconsistent with the Kraepelinian dichotomy is the view that there is significant pathophysiological heterogeneity among the psychoses (118). To explain the data, however, this heterogeneity would have to be on the order of what is observed among the mentally retarded. Although mental retardation is clearly associated with multiple pathophysiological processses and determinants of those processes, it is defined by similar performance on certain tests. For the psychoses, they may also derive from multiple pathophysiological processes and determinants but are categorized loosely together because of certain behaviors (hallucinations, delusions, aberrations in affect) shared by all, so their underlying heterogeneity is obscured.

As none of these possibilities can be clearly discarded, future studies of the pathophysiology or determinants of psychosis should not presume a single model. Thus, future research either should focus on the neurology of specific psychopathological phenomena (the study of which transcends the discrete disease issue) or, if focusing on disease entities, should have a flexible design. The strategies of extensively studying pure or mixed pedigrees and studying people at high risk for psychosis appear to be the most powerful approaches (119, 120), ultimately applying focused molecular genetic techniques to pedigrees with converging biological data. Whether these techniques will be as successful for the psychoses as they have been for many nonpsychiatric diseases remains to be established.

# Should Caffeine Abuse, Dependence, or Withdrawal Be Added to *DSM-IV* and *ICD-10?*

John R. Hughes, M.D., Alison H. Oliveto, Ph.D., John E. Helzer, M.D., Stephen T. Higgins, Ph.D., and Warren K. Bickel, Ph.D.

Objective: *The authors reviewed basic science and clinical data on caffeine abuse, dependence, and withdrawal in order to make a conclusion about whether these disorders exist and should be included in* DSM-IV *and* ICD-10. Method: *Studies were located through computerized searches, reference sections of published articles, and written requests.* Results: *The studies show that abstinence from caffeine induces a withdrawal syndrome of headache, fatigue, and drowsiness which begins within 12–24 hours and lasts about 1 week. The syndrome can be severe and appears to be one reason for continued use of coffee. The prevalence of this caffeine withdrawal syndrome is unknown. Use of caffeine may aggravate some common behavioral and medical disorders. In double-blind tests, a subset of coffee and soda drinkers reliably self-administered caffeinated beverages in preference to uncaffeinated beverages. Clinical indicators of dependence, such as difficulty stopping use of caffeine and use despite harm, have not been documented.* Conclusions: *Caffeine withdrawal but not caffeine abuse or dependence should be included as a diagnosis in* DSM-IV *and* ICD-10. *Future research should focus on whether some caffeine users exhibit clinical indicators of drug dependence.*

(Am J Psychiatry 1992; 149:33–40)

Caffeine is the most widely used drug in the world. For example, over 85% of Americans ingest caffeine daily, and the average caffeine intake is approximately 200 mg/day (1, 2). Excessive caffeine intake is especially prevalent among psychiatric patients (3–5); 22% of psychiatric inpatients use more than 750 mg/day (5), compared to 9% of the general population (2). Caffeine can be ingested from brewed coffee (100 mg/6 oz), instant coffee (65 mg/6 oz), tea (40 mg/6 oz), soda (50 mg/12 oz), and over-the-counter analgesics, antihistamines, stimulants, and weight-loss aids (50–200 mg/tablet). Whether caffeine is a drug of abuse or dependence and whether cessation of caffeine use can induce withdrawal symptoms have been examined in previous reviews (6–8); however, none of these has discussed caffeine use disorders in the light of *DSM* or *ICD* criteria.

Many definitions of and criteria for drug abuse, dependence, and withdrawal have been proposed. To increase the comprehensiveness of this review, broad definitions of these terms are used. "Withdrawal" refers to time-limited effects due to cessation (9). Drug tolerance is usually associated with withdrawal (10). "Abuse" refers to harmful or hazardous use (*ICD-10, DSM-III-R*) or use for socially disapproved reasons (10). "Dependence" refers to a constellation of symptoms outlined by Edwards and colleagues (11, 12), *ICD-10*, and *DSM-III-R* that includes withdrawal, tolerance, and abuse. "Dependence" in these schemas also focuses on loss of control over drug use, excess time in procuring or preparing the drug, progressive neglect of self because of drug use, narrowing of the pattern of drug use, and rapid reinstatement of drug dependence upon relapse.

## CAFFEINE WITHDRAWAL

### *Basic Science Criteria*

The *DSM-III-R* definition of withdrawal is "development of a substance-specific syndrome that follows the cessation of, or reduction in, intake of a psychoactive substance that the person previously used regularly" (p. 118).

---

Presented at the annual meeting of the American Psychological Association, Boston, Aug. 13, 1990. Received Oct. 23, 1990; revision received April 18, 1991; accepted April 29, 1991. Other criteria include demonstration of relief of the syndrome by the readministration of the drug, rebound or "overshoot" effects, and physical changes (9).

*Experimental induction of withdrawal symptoms.* Six studies have examined caffeine deprivation in nonhuman subjects chronically treated with caffeine (13, 14). Most found that deprivation of caffeine decreased locomotor activity or disrupted performance to below baseline levels (13, 14). We are unaware of studies of changes in physiological, hormonal, or biochemical processes in nonhuman subjects.

In over 14 experimental trials with human beings, headache, decreased arousal, and fatigue consistently occurred upon cessation of caffeine use (14). These symptoms occurred during well-controlled, blind deprivation of caffeine alone (e.g., substitution of decaffeinated coffee) and were reversed by readministration of caffeine. Several other withdrawal symptoms have been reported, including anxiety, nausea, and craving for caffeine, but these have not been as well documented (14). Caffeine withdrawal symptoms begin 12–24 hours after deprivation, peak at 20–48 hours, and last about 1 week (14). One study (15) showed that in some coffee drinkers, withdrawal symptoms reliably occurred with repeated substitutions of decaffeinated coffee (i.e., on five or six of six tests).

Cessation of caffeine also has biochemical and physiological effects, such as increased blood pressure (16), 3-methoxy-4-hydroxyphenylglycol (MHPG) (17), and heart rate orientation response (18) and decreased β-adrenoreceptor sensitivity (19). Other studies have failed to find effects of caffeine deprivation on biochemical and physiological measures such as blood pressure (20), levels of catecholamines (20), heart rate (20), and muscle tension (21).

Several studies (18, 22–24) have shown decreases in performance on vigilance and psychomotor tasks after subjects stopped using caffeine. In addition, in most of the studies which have shown that acute doses of caffeine can improve performance, subjects have been deprived of caffeine for 12 hours. Thus, these studies may have been demonstrating reversal of withdrawal effects rather than direct effects of caffeine (25).

Factors predisposing to withdrawal symptoms have not been well studied. Two experimental studies (26, 27) reported that the severity or probability of withdrawal effects is related to the maintenance dose of caffeine, but other studies (15, 24) did not find this. In two studies (27, 28), withdrawal symptoms occurred at doses of caffeine as low as 100 mg/day.

One case report (29) suggested that neonatal withdrawal symptoms could occur after heavy maternal caffeine intake; however, empirical studies are lacking. In addition, neonatal withdrawal symptoms have not been found with maternal use of other stimulants (e.g., cocaine, amphetamine, and nicotine).

Several mechanisms could account for the symptoms of caffeine withdrawal: greater sensitivity to endogenous adenosine (caffeine is an adenosine antagonist) (30), changes in adrenergic sensitivity (19), or, in the case of headaches, increased cerebral blood flow (31). Although there are some data supporting these mechanisms, the data are not yet convincing.

*Tolerance.* Tolerance is usually associated with withdrawal. Tolerance is defined in *DSM-III-R* as the "need for markedly increased amounts of the substance (i.e., at least a 50% increase) in order to achieve intoxication or desired effect, or markedly diminished effect with continued use of the same amount" (p. 168). The working draft of *ICD-10* has a similar definition.

Several studies (32–34) have documented tolerance to the effects of caffeine in nonhuman subjects. In addition, repeated dosing of caffeine in nonhuman subjects increases the number and sensitivity of brain adenosine receptors, which might be a mechanism for the development of tolerance (35, 36).

In humans, experimental administration of caffeine induces tolerance to hemodynamic and other physiological effects of caffeine (20). An experimental demonstration of tolerance to the behavioral effects of caffeine in humans has not been reported. Previous studies have indicated that caffeine has fewer negative subjective effects in persons who drink large amounts of coffee than in those who drink small amounts (37–40); however, whether this is due to acquired tolerance or to self-selection by individuals differing a priori in sensitivity to caffeine is unclear. Finally, studies linking the degree of caffeine tolerance and that of caffeine withdrawal symptoms have not been reported.

### *Clinical Criteria*

*Severity of withdrawal symptoms. DSM-III-R* states that caffeine withdrawal was not included because "although the existence of a caffeine withdrawal headache is well established, the syndrome is usually not severe enough to warrant clinical attention" (p. 138). However, several double-blind, placebo-substitution trials have documented the occurrence of caffeine withdrawal headache, drowsiness, or fatigue that interfered with normal function and was at times incapacitating. In the first report (41), 22 men were given 600–750 mg/day of caffeine for 6–7 days, and then placebo was substituted. On 21 (55%) of 38 trials, headache "as severe as the subject had ever had" was reported. In six (27%) of the subjects, the headache was consistently accompanied by some degree of nausea, and vomiting occurred in two (9%) of the subjects.

In four more-recent studies, decaffeinated coffee was substituted for caffeinated coffee in a double-blind manner. In the first study of six heavy coffee drinkers (22), on six (10%) of the 63 tests the headache was rated as strong. In a second study of moderate coffee drinkers (24), severe headaches were reported on eight (15%) of 55 trials, severe drowsiness on nine (16%) of the trials, and severe fatigue on six (11%) of the trials. In a third study (15), two of 10 subjects dropped out because they had headaches on decaffeinated-coffee days that were severe enough to prohibit productive work at the subjects' jobs. In a fourth study of subjects taking 100 mg/day of caffeine in capsules (42), headache and fatigue occurred even upon deprivation of this low dose. In fact, "the headache, lethargy and nausea experienced after placebo substitution in six of the seven subjects were incompatible with normal functioning; subjects occasionally reported going to bed early with flu-like symptoms and two subjects reported vomiting. We judge the peak level of disruption encountered by six of the seven subjects to be clinically significant" (27).

*Prevalence of withdrawal symptoms.* Among retrospective surveys, an early study (43) found that 8%–9% of 239 housewives who drank coffee reported headaches after cessation, and 38% stated that they would feel "half-awake" if they stopped coffee use. Among headache patients, 20% stated that lack of coffee would result in headaches (41). Among psychiatric inpatients, 20% reported headaches upon caffeine cessation (44). Such survey data may actually underestimate the prevalence of withdrawal symptoms, as many caffeine users may be unaware that intermittent drowsiness, headaches, and fatigue could be due to the absence of caffeine.

Among prospective studies, a study of postoperative headache found that the prevalence of headaches increased from 0% in nonusers of caffeine to 43%–46% in those who used 200–1,000 mg/day to 73% among those who used more than 1,000 mg/day (26). In three trials, among nonpatient (i.e., volunteer) moderate coffee drinkers (3–7 cups/day), the prospective prevalence of headaches was 23%–56%; of drowsiness, 38%; and of fatigue, 38% (15, 24, 45). The prospective prevalence of caffeine withdrawal headaches following cessation of heavy caffeine use (more than 600 mg/day) in patient samples has been reported to be between 82% and 100% (41, 46).

*Withdrawal symptoms and self-administration of caffeine.* In three studies (15, 22, 24), subjects who had withdrawal headaches, drowsiness, or fatigue upon placebo substitution were subsequently more likely to self-administer caffeinated coffee in preference to decaffeinated coffee than were subjects who did not experience these withdrawal symptoms. In two studies (15, 24), the occurrence of withdrawal effects was followed by self-administration more than 80% of the time; however, on 30%–40% of occasions, self-administration occurred in the absence of withdrawal symptoms. Thus, the presence of withdrawal symptoms is highly predictive of caffeine self-administration, but the absence of withdrawal symptoms does not predict the absence of caffeine self-administration.

### *Conclusions With Respect to Caffeine Withdrawal*

At the present time, there appears to be sufficient evidence to justify inclusion of a caffeine withdrawal syndrome in *DSM-IV* and *ICD-10*, with headache, decreased arousal, and fatigue listed as the valid symptoms. These symptoms have been shown to be due to the specific deprivation of caffeine, they have a characteristic time-limited course, they can occur at moderate caffeine intakes, they can occur in a substantial proportion of coffee drinkers, and they appear to contribute to the self-administration of caffeine. Finally, the earlier rationale for not including caffeine withdrawal—i.e., the symptoms are not severe—appears not to be true. Experimental tests of tolerance to the behavioral effects of caffeine and further study of the association of tolerance and withdrawal symptoms, the biochemical mechanisms of withdrawal symptoms, and the prevalence of symptoms of caffeine withdrawal are needed.

### *Inclusion of the Caffeine Withdrawal Syndrome and the Goals of* DSM

*Clinical usefulness for making treatment and management decisions.* Heavy caffeine use appears to be quite prevalent among psychiatric patients (3–5) and alcohol and drug abusers (47, 48). Many psychiatric, alcohol/drug abuse, and medical inpatient units prohibit caffeinated coffee; thus, some patients may be forced into a caffeine withdrawal syndrome when entering these units. This could interfere with the diagnosis and treatment of such patients, since the symptoms of caffeine withdrawal (headache, fatigue, and drowsiness) could mimic or falsely exaggerate symptoms of anxiety, depression, dementia, delirium, stimulant withdrawal, or drug-induced sedation. Having a diagnosis of caffeine withdrawal syndrome would sensitize clinicians to this possibility.

Prevalence is a consideration for clinical usefulness. On the basis of the data described earlier, a conservative estimate of the prevalence of caffeine withdrawal symptoms is that 5% of caffeine users develop headache, drowsiness, or fatigue upon cessation. Even such a low prevalence is important, given that 85%–90% of U.S. adults use caffeine daily.

*Acceptability to clinicians and researchers.* Clinicians and scientists may welcome the inclusion of a caffeine withdrawal syndrome, since other stimulants (e.g., amphetamine and cocaine) have accepted withdrawal syndromes but caffeine does not. Opposition to inclusion of a caffeine withdrawal syndrome might come from those who believe that it is less severe than other withdrawal syndromes. We are unaware of survey or experimental comparisons of caffeine with other withdrawal syndromes. However, the data we have cited suggest that symptoms of caffeine withdrawal can be severe and can interfere with role functioning. In addition, the data suggest that the presence of caffeine withdrawal symptoms contributes to the continued use of caffeinated beverages.

Opposition to including a caffeine withdrawal syndrome might also be due to a fear that its acceptance implies acceptance of caffeine as a drug of dependence. In recent years, many drugs that are not drugs of dependence have been identified as producing withdrawal symptoms upon cessation (e.g., antidepressants and antipsychotics) (49, 50). Thus, accepting that withdrawal of a drug can produce symptoms no longer necessarily implies accepting that it is a drug of dependence.

## CAFFEINE ABUSE

### *Basic Science Criteria*

The *DSM-III-R* criteria for psychoactive substance abuse are "continued use . . . despite knowledge of having a persistent or recurrent social, occupational, psychological, or physical problem that is caused or exacerbated by use of the substance" and "recurrent use of the substance in situations when use is physically hazardous (e.g., driving while intoxicated)" (p. 169). A working draft of *ICD-10* defines harmful use as "a pattern of use which is causing damage to health. The damage may be physical or mental." Two basic science areas relevant to abuse are caffeine psychoactivity and harmful medical effects.

*Psychoactive effects of caffeine.* Basic science definitions of psychoactivity usually refer to the ability to discriminate between a drug and placebo on the basis of the drug's CNS effects. Nonhuman subjects readily discriminate caffeine from placebo and respond as if caffeine has weak amphetamine-like effects (51–54). Humans also readily discriminate caffeine, even at very low doses (e.g., 10–56 mg) (42, 55).

In studies of self-reported effects, single doses (100–400 mg) of caffeine produce slight increases in elation, positive mood, and amphetamine-like effects (39, 55–60). These effects are generally less consistent and of a smaller magnitude than those seen with amphetamine. In addition, at these same doses, caffeine often produces several presumably aversive effects (e.g., increased anxiety and dysphoria) (61, 62).

*Harmful effects of caffeine.* Reviews vary widely in their conclusions about whether caffeine can cause physical disorders (8, 63). However, the *DSM-III-R* criteria for abuse include the ability of a drug not only to initiate a new disorder but also to aggravate an existing disorder. With respect to the latter category, a recent survey (64) indicated that more than 75% of physician specialists recommended cessation of caffeine for patients with several common disorders: anxiety, arrhythmias, esophagitis, fibrocystic disease, insomnia, palpitations, and tachycardia.

Behavioral disorders resulting from caffeine use are well recognized. As indicated in *DSM-III-R* (p. 139), caffeine use of even as little as 250 mg/day can cause restlessness, nervousness, excitement, insomnia, flushed face, diuresis, gastrointestinal disturbance, muscle twitching, rambling flow of thought or speech, tachycardia or cardiac arrhythmia, periods of inexhaustibility, and psychomotor agitation.

### *Clinical Criteria*

Clinical indications for drug abuse include use despite problems from a drug, hazardous use, and unsanctioned (i.e., socially disapproved) use (10, 12).

*Use despite problems.* Case reports describe substance abusers (65) and anorexic patients (66) who have persistent, very high caffeine intakes with resultant symptoms of intoxication. In some cultures, caffeine capsules are abused and have been linked to psychoses and anxiety disorders (67). On the other hand, whether patients persist in the use of caffeine despite physicians' recommendations has not been reported.

*Hazardous use.* Since caffeine intoxication can produce restlessness, excitement, muscle twitches, rambling flow of thought, and psychomotor agitation, it is possible that these consequences could impair driving, working with machinery, etc. However, case reports of such events have not been published.

*Unsanctioned use.* A urine screen survey found very high blood levels of caffeine (more than 12.5 mg/ml) in 5% of competitive bicyclists (68). A study of cocaine samples found that caffeine was a common adulterant (69).

### *Summary of Caffeine Abuse Study Results*

Caffeine can produce positive mood and amphetamine-like effects, but these appear to be less robust than those associated with prototypic drugs of abuse. Case reports indicate instances of repeated caffeine intoxication; however, the prevalence of such phenomena is unclear. Persistent use of caffeine in the face of a known illness aggravated by caffeine has not been documented, nor have caffeine-induced accidents been documented.

## CAFFEINE DEPENDENCE

### *Basic Science Criteria*

Demonstration that a drug serves as a reinforcer is thought to be crucial to definitions of drug dependence (70). Reinforcing effects are inferred when subjects consistently self-administer a drug at a rate greater than or in preference to placebo.

In nonhuman subjects—even those previously trained to self-administer opioids, cocaine, etc.—caffeine either does not serve as a reinforcer or does so marginally or inconsistently (71). Two early studies (72, 73) suggested that in humans, caffeine in coffee can serve as a reinforcer, but these studies lacked adequate controls (i.e., decaffeinated coffee or return-to-baseline conditions). A third study (60) used preference for ingesting caffeine capsules over placebo capsules to infer reinforcing effects among light users of caffeine and found no preference for 100-mg or 300-mg caffeinated capsules. A fourth study (74) compared the rate of self-administration of decaffeinated coffee to that of coffee with 25, 50, 100, 200, and 400 mg of caffeine added and found slight increases in administration of the 50-mg and 100-mg doses.

In three well-controlled studies by Griffiths et al. (22, 45, 75), a subset of subjects consistently self-administered caffeinated coffee or capsules rather than placebo during double-blind tests. Four studies by our group (24, 76–78) replicated these effects and extended them to low doses (25–50 mg). In several of these studies, caffeine self-administration was maintained under double-blind conditions across many independent tests (e.g., 12–26 tests) for long periods of time (e.g., 6 months). Although these results were quite robust in some individuals, reasons for individual differences in reinforcing effects have not been established (45, 76, 77).

The magnitude of reinforcing effects from caffeine can be estimated by noting how hard human beings will work to obtain caffeine. In one study (75), the amount of work required in order to obtain caffeinated coffee, decaffeinated coffee, caffeine capsules, or placebo capsules was increased over time. Self-administration of placebo capsules dropped off quickly, self-administration of caffeinated coffee persisted the longest, and decaffeinated coffee and caffeine capsules were self-administered at an intermediate level. In another study (79), increasing the amount of work required to obtain coffee decreased coffee consumption to an extent similar to that obtained with cigarettes. In that study, subjects made up to 2,500 lever pulls for 2-oz servings of caffeinated coffee.

### *Clinical Criteria*

The *DSM-III-R* and *ICD-10* dependence criteria of withdrawal symptoms, tolerance, use to avoid withdrawal symptoms, use despite knowledge of harm, and hazardous use have already been discussed. We now discuss the five other clinical criteria in *DSM-III-R* or *ICD-10.*

*Loss of control.* This criterion is operationalized in *DSM-III-R* as "substance often taken in larger amounts or over a longer period than the person intended" (p. 167) or "persistent desire or one or more unsuccessful efforts to cut down or control substance use" (p. 168).

There are no reports of whether some caffeine users would describe themselves as losing control of their caffeine intake. Some case reports and clinical reviews suggest that there are some patients who wish to quit caffeine but are unable to do so and that relapse rates are high (44, 80). However, neither prospective studies of attempts to stop using caffeine nor survey data on the prevalence of attempts to stop using caffeine and their success rates are available. Nor are there any data on the difficulty that caffeinated coffee users have with switching to decaffeinated coffee.

*Time with drug.* This criterion is defined in *DSM-III-R* as "a great deal of time spent in activities necessary to get the substance . . . , taking the substance . . . , or recovering from its effects" (p. 168). Application of this criterion to readily available licit drugs is problematic. Although caffeinated beverages can be quickly made, in some historical periods and in some present cultures, preparation and consumption of coffee/tea have been described as time-consuming (8). To our knowledge, instances of spending a great deal of time on preparation and use of beverages containing caffeine have not been reported in the recent Western literature.

*Progressive neglect.* This criterion is defined in *DSM-III-R* as "important social, occupational, or recreational activities given up or reduced because of substance use" (p. 168). Again, this criterion is not readily applicable, as caffeine is widely available, can be used in social situations, and produces no aftereffects. Instances of progressive neglect due to caffeine use have not been reported.

*Narrowing of the repertoire.* This criterion is defined in a draft of *ICD-10* as "a narrowing of the personal repertoire of patterns of use." The construct is not included in *DSM-III-R.* Caffeine users do appear to have very regular patterns of use (74); however, the narrowing-of-repertoire criterion implies resistance to changes in the pattern of drug intake. Although this has not been tested, most coffee drinkers appear to be flexible with respect to environmentally induced changes in the timing of their caffeine intake, perhaps because caffeine is available in almost all settings.

*Rapid reinstatement.* Rapid reinstatement is defined in the *ICD-10* draft as "evidence that return to use after a period of abstinence leads to more rapid reinstatement of other features of the syndrome than occurs with nondependent individuals." This construct is also not included in *DSM-III-R.* At present there are no studies of cessation of caffeine and relapse back to caffeine use; thus, no data on this construct are available.

### *Construct Validity of the Dependence Syndrome*

One important indication of the validity of a disorder is the presence of familial patterns or biological markers. Several studies (81–86) have noted higher concordance rates of coffee use among monozygotic twins than among dizygotic twins. Heritability coefficients were quite similar across most studies: 0.46–0.49. It is important to note that these studies examined coffee use—not abuse, dependence, or withdrawal. Thus, a genetic propensity to use caffeine has been suggested, not a propensity to become dependent.

Other studies have noted a higher concordance among monozygotic twins for tolerance to sleep disruption from coffee (87). Another piece of genetic evidence is that taste sensitivity to caffeine is under strong control of genotype (88). Finally, although this is not direct evidence, variations in metabolism of caffeine across users and nonusers occur (89), and persons with faster clearance appear to be more tolerant to the sleep disruption from coffee (90). However, an earlier study did not find this (39).

### *Summary of Caffeine Dependence Study Results*

Although caffeine has not been shown to be a reliable reinforcer in nonhuman subjects, in human beings caffeine serves as a very reliable reinforcer for some individuals. Analyses of the strength of caffeine's reinforcing effects have just begun; thus, it is not possible to conclude whether, in some individuals, caffeine is as strong a reinforcer as nicotine, alcohol, etc. As indicated earlier, the evidence for withdrawal symptoms and for behavioral harm from caffeine is robust. The evidence for tolerance and physical harm is suggestive. In contrast to these positive results from basic science studies, clinical data on traditional indicators of dependence are clearly lacking.

## CAFFEINE ABUSE AND DEPENDENCE

### *Conclusions With Respect to Caffeine Abuse and Dependence*

At the present time there is insufficient evidence to include caffeine abuse or dependence in *DSM-IV*. This conclusion is based mainly on the notion that a new disorder should not be included in *DSM* or *ICD* until there is a substantial and compelling database. This is especially important with disorders that could be applied to large numbers of individuals. At present a substantial basic research database exists for caffeine dependence (i.e., caffeine can serve as a reinforcer, produce withdrawal, and cause behavioral harm), but a clinical database is almost completely absent. The type of clinical data that would be necessary for adding caffeine dependence include empirical evidence that a substantial proportion of coffee drinkers 1) try to stop and cannot, 2) have difficulty switching to decaffeinated coffee, and 3) use caffeine despite knowledge that they have health problems which are aggravated by caffeine. Other data of interest would be 4) heavy coffee drinkers' ratings of the difficulty of stopping caffeine intake compared to stopping cigarette smoking or drinking alcohol, 5) whether tolerance to important behavioral effects (e.g., relief of fatigue) occurs, 6) whether coffee use escalates over time, 7) how often coffee is used to avoid withdrawal symptoms, and 8) what the prevalence of caffeine dependence is.

### *Exclusion of Caffeine Abuse and Dependence and the Goals of* DSM

*Clinical usefulness for making treatment and management decisions.* Although we have not recommended the inclusion of the diagnoses of caffeine abuse and dependence, some persons might state that their inclusion is needed in order to be consistent with the recent emphasis in medical "wellness" and drug-free alcohol/substance abuse programs on complete abstinence from all drugs. In addition, there is some evidence that caffeine use promotes alcohol use and abuse (8, 47, 91). In a similar vein, inclusion would be consistent with treatment programs that emphasize organismic rather than drug factors in the genesis and maintenance of alcohol/drug abuse. In addition, caffeine intake is quite high in some subcultures (8); thus, caffeine dependence might actually be relevant in these settings. Finally, and perhaps most importantly, one could argue that inclusion of caffeine abuse would promote identification of patients who repeatedly experience intoxication and would suggest that in addition to treatment for caffeine intoxication, such patients need acute treatment for an abuse/dependence problem.

On the other hand, one clinical reason not to include caffeine abuse and dependence is that caffeine intoxication is already included in *DSM-III-R* and that such a diagnosis should remind psychiatrists that excessive caffeine use can mimic several psychiatric conditions, including anxiety disorders and drug withdrawal. A second clinical reason for not including caffeine abuse and dependence is that, at present, only a few treatments for caffeine abuse and dependence have been tested (92, 93). Whether treatments used for other drugs (e.g., 12-step programs, behavioral therapy, pharmacological replacement) would be efficacious is debatable. Thus, the therapeutic benefits of a diagnosis of caffeine abuse or dependence are not clear.

Finally, at present patients with symptoms of caffeine dependence can be given the *DSM-III-R* diagnosis of psychoactive substance dependence not otherwise specified. This residual category is for disorders that occur infrequently. Thus, a determination of the prevalence of caffeine dependence phenomena both in treatment settings and in the general population would be helpful in deciding whether a new disorder should be created or whether instances of caffeine dependence are so infrequent that they should continue to be put in this residual category.

*Acceptability to clinicians and researchers.* A decision to exclude caffeine abuse and dependence could provoke negative comments from primary care physicians, psychiatrists, and substance abuse clinicians who have patients who recognize that caffeine is aggravating their disorders, who have severe headaches upon cessation of caffeine, or who are unable to stop caffeine use. Such clinicians might accuse *DSM-IV* of being inconsistent in its handling of various drug use problems or of being politically cowardly.

A decision to include caffeine abuse and dependence may provoke negative comments from coffee manufacturers, the general public, and some substance abuse clinicians. Coffee manufacturers will obviously fear a public debate like that which occurred with respect to tobacco. The general public and some substance abuse clinicians will state that inclusion of caffeine dependence trivializes other more damaging substance use disorders, promotes the view of *DSM* as a tool for psychiatrists to aggrandize diagnostic territory, and undermines the credibility of APA. These groups will focus on the lack of clinical information on caffeine abuse and dependence and the absence of studies comparing the relative strengths of caffeine dependency versus alcohol, nicotine, and other dependencies.

## FINAL COMMENT

Whether caffeine withdrawal, caffeine abuse, or caffeine dependence should be added to the *DSM* or *ICD-10* classifications will be a controversial topic. This article was written in the belief that empirical data and established criteria for acceptance of disorders are better guides for such a decision than a priori beliefs or philosophical positions.

# Attempted Suicide Among Young Adults: Progress Toward a Meaningful Estimate of Prevalence

Patrick J. Meehan, M.D., Jane A. Lamb, Ph.D., Linda E. Saltzman, Ph.D., and Patrick W. O'Carroll, M.D., M.P.H.

*Objective: The results of epidemiologic surveys on attempted suicide are often difficult to interpret; they compare and provide varying estimates of the prevalence of attempted suicide. The authors sought to estimate the prevalence of attempted suicide in a young adult population and to define more precisely what respondents mean when they report a suicide attempt. Method: Survey respondents were a representative sample of all 18–24-year-old freshman students at a major public university. The self-administered, anonymous survey included questions about suicidal thoughts and behaviors and about any injury and need for medical care resulting from reported attempts. Results: Of the 694 respondents, 374 (54%) reported having ever considered suicide and 181 (26%) had considered suicide during the preceding 12 months. Thirteen (2%) students reported having attempted suicide during the preceding 12 months, and 72 (10%) reported ever having attempted suicide. The number of students answering affirmatively to questions about injuries sustained, medical care sought, and hospitalization as a result of attempted suicide decreased progressively: only 18 (3%) students reported having ever sought medical care due to a suicide attempt, and seven (1%) were ever hospitalized. Conclusions: The prevalence of self-reported attempted suicide is not representative of the prevalence of self-injury and provides little information concerning the seriousness of the attempt. The use of specific questions similar to those used in this study should be considered in future surveys.*

(Am J Psychiatry 1992; 149:41–44)

Attempted suicide is not only a major risk factor for subsequent completed suicide (1, 2) but also a morbid health event that results in personal suffering and considerable economic cost (3). Epidemiologic surveys provide useful information about the magnitude of the problem of attempted suicide in the general population and among specific populations such as students.

Although previous surveys have varied considerably in methodology and in the questions asked, some estimates of the prevalence of self-reported attempted suicide are available. The National Adolescent Student Health Survey (4), a survey of a national probability sample of eighth- and tenth-grade students, yielded an estimated lifetime prevalence of attempted suicide among high school students of about 14%. One population-based study, the Epidemiologic Catchment Area (ECA) study (5), which involved five geographic areas, found a lifetime prevalence of attempted suicide among all adults of 2.9% and a prevalence among 18–24-year-olds of 3.4%. Several surveys of specific college student

Presented at the Epidemic Intelligence Service Conference, Centers for Disease Control, Atlanta, April 1990. Received Feb. 20, 1991; revision received June 25, 1991; accepted July 26, 1991. From the Division of Injury Control, Center for Environmental Health and Injury Control, Centers for Disease Control, Public Health Service, U.S. Department of Health and Human Services, Atlanta, and the Department of Social Work, University of Nevada, Reno. Address reprint requests to Dr. Meehan, Division of Public Health, 6 Hazen Drive, Concord NH 03301.

The authors thank Joseph Q. Jarvis, M.D., Dr.P.H., for his help and advice and Patricia L. Holmgreen for her assistance with data management.

populations have been done (6–9); these provide estimated lifetime prevalences of self-reported attempted suicide as high as 15%.

There is a spectrum of suicidal thoughts and behaviors that begins with ephemeral thoughts about suicide and proceeds to attempted suicide without injury, to attempted suicide with serious injury, and finally to completed suicide. Results of surveys designed to estimate the incidence or prevalence of suicidal thoughts (ideation) and suicidal behaviors are often difficult to interpret and compare because they simply ask, "Have you attempted suicide?" Rarely is an attempt made to elucidate the seriousness of suicidal intent or to ascertain what respondents mean by "suicide attempt" in terms of the severity of the outcome. This problem is exemplified by the paradoxically higher estimated lifetime prevalence of attempted suicide for younger respondents than for older respondents, as in the ECA study (5). It is possible that some thoughts or behaviors reported as attempted suicide by younger respondents are not reported as such by older respondents.

Possible approaches to clarifying what respondents mean when they report having attempted suicide include specifically defining the term "suicide attempt" for the respondents, using more precise terminology when asking about attempted suicide, and specifying the outcome of the attempted suicide through a series of increasingly specific questions. In the present study, we employed the latter two approaches in a survey addressing suicidal thoughts and behavior among college students. To define attempted suicide for the respondents, we asked specifically whether the respondents had "attempted to take their own lives" rather than whether they had "attempted suicide." We also asked a series of increasingly specific questions about the outcomes of reported attempts, in terms of injury, medical care received, and hospitalization. By asking more precise questions about attempted suicide and by allowing respondents to clarify what they meant by "suicide attempt" in terms of injury outcome and medical care received, we tried to get more interpretable estimates of the prevalence of suicidal behaviors.

## METHOD

We surveyed a representative sample of students from a single public university in Nevada to determine the annual and lifetime prevalence of suicidal ideation and attempted suicide among the respondents. During the week in which the survey was administered, there were 61 freshman English classes, with 1,218 students enrolled at the beginning of the semester. Each instructor of freshman English was asked to have his or her class participate. Students were not told about the survey until the day it was administered. The instructors of seven classes chose not to invite their students to participate for a variety of reasons, none of which had to do with recent suicides or suicide attempts. Of the 804 students present on the day of the survey in the remaining 54 classes, 774 (96%) completed forms. This represented 64% of the enrolled freshmen. Since the survey was anonymous, we were not able to obtain demographic or other information for the students who were not in class on the day the survey was administered.

The survey was administered during regular class periods in a single week. Before distributing the questionnaires, the instructor in each class read a brief, standardized introduction indicating that the survey was voluntary and anonymous. Participants were then given a self-administered questionnaire that included written instructions and enough information about the study to enable them to make an informed decision regarding their participation in it. Students were told that the survey was a joint project of state and federal public health agencies. No personal identifiers were put on the questionnaires. The respondents were asked to return the questionnaires (completed or blank) in an envelope that was provided.

The survey instrument included a set of demographic items, questions about the respondent's history of suicidal thoughts and behaviors, and a series of questions intended to examine certain potential risk factors for attempted suicide. The present analysis is limited to data on the respondents' histories of suicidal thoughts and behaviors. The questions about suicidal ideation and attempted suicide are listed in appendix 1.

Lifetime and annual prevalences of specific suicidal thoughts, behaviors, and outcomes were calculated for the 694 respondents who were 18–24 years of age. Outcomes in terms of injury and medical care received were assumed to apply to the most recent attempted suicide. This may have resulted in a slight overestimation of the annual prevalence of injury and medical care received because of attempted suicide because, in a few cases, there were not only attempts in the preceding 12 months but also more remote attempts. Statistical significance testing was done by using the two-tailed Fisher exact test or the Mantel-Haenszel chi-square.

## RESULTS

Lifetime prevalences of suicidal thoughts and behaviors are presented in table 1. In response to the question, "Have you EVER had thoughts of taking your life, even if you would not really do it?" 53.9% of the respondents answered affirmatively. Somewhat fewer respondents reported having ever thought of a specific way of taking their own lives, and the lifetime prevalence of actual attempted suicide was 10.4%. The proportion of respondents who reported ever suffering injury or illness as a result of attempting suicide was 4.6%, but the proportion who reported seeking medical care as a result of a attempted suicide was 2.6%. Only 1.0% of the respondents reported an overnight hospitalization after attempted suicide.

Of the 72 respondents who reported ever having attempted suicide, 44% actually suffered an injury, 25% sought medical care, and 10% were admitted to the

hospital. Thoughts of suicide, attempted suicide, attempted suicide with injury, and attempted suicide resulting in the use of medical care were all significantly more common among women (table 1).

Similar patterns were seen for the prevalence of suicidal thoughts and behaviors during the 12 months preceding the survey (table 1). The prevalence of attempted suicide was much lower than the prevalence of suicidal ideation. Suicide attempts reported to have occurred in the 12 months preceding the survey resulted in injury approximately half the time, rarely resulted in the use of medical care, and in no case caused overnight hospitalization. Attempted suicide in the 12 months preceding the survey was also more common among women than men.

## DISCUSSION

We found that the prevalence of self-reported attempted suicide in this study did not reflect the prevalence of self-injury due to a suicide attempt. Moreover, had we not extended our series of questions beyond simply inquiring about past history of attempted suicide, we would have learned nothing about what the respondents meant in terms of the seriousness of the attempt. In fact, we found a cascade of decreasing prevalence as the severity of outcome increased in terms of injury and need for medical attention.

These findings merit emphasis because they profoundly affect the way we should interpret results of the many surveys that have been done to estimate the prevalence of attempted suicide. The high prevalence of self-reported attempted suicide among certain population groups, such as adolescents, correctly highlights the magnitude of this public health problem.

Our results indicate, however, that the nature of the problem is not one of large numbers of injured people, although this may be the impression generated by reports of a lifetime prevalence of attempted suicide among young adults of up to 15% (7). The high prevalence of attempted suicide is a serious problem because it reflects a considerable amount of psychological suffering and desperation for most suicide attempters and because suicide attempters are at high risk of later completed suicide (1, 2).

We found a disparity between the proportion of respondents who reported having attempted suicide and the proportion who suffered an injury or sought medical care as a result of the suicide attempt despite our having asked very specifically about an attempt on one's life rather than simply asking about "suicide attempts." This should be considered when designing future surveys. To obtain information about suicide attempts that actually involve self-harm, a series of questions similar to the ones used in this survey may be necessary.

Rarely have past surveys on attempted suicide addressed the methodological problem of defining what is meant by respondents when they report having attempted suicide. To ascertain the lethality of the respondent's intent, one community survey (10) asked the questions, "Have you ever deliberately harmed yourself, but in a way that stopped short of a real intent to take your life?" and "Have you ever made an intentional attempt to take your life?" Another cross-sectional study of a relatively small, nonrandom sample of high school students found a disparity similar to that found in our study between the frequency of reported attempted suicide and use of medical care as a result of the attempt (11).

Our estimated prevalences of suicidal ideation and attempted suicide are comparable to the highest estimates that have been found in other studies of attempted suicides among young adults. The finding that women have a higher prevalence of attempted suicide than men is consistent with findings from past studies of attempted suicide (5, 12).

Since participation in this survey was anonymous, we could not contact students who were absent on the day of the survey or students who had dropped English earlier in the semester. This limitation may result in a bias in our estimation of prevalences of suicidal thoughts and behaviors, but the direction of this potential bias is not known. Also, we could not compare the demographic characteristics of the study participants with those of students who were not in class on the day of the survey. Our 96% response rate among the freshman students who attended class on the day of the survey, however, suggests that this survey is highly representative of this group.

Another limitation that this survey shares with other confidential surveys (13) is that the responses could not be externally validated. Future studies are needed to establish the validity of self-reported suicidal behaviors in general. If specific and quantifiable outcomes (such as those used in our study) are found to be valid, they could be used to provide meaningful surveillance data through periodic surveys.

## APPENDIX 1. Questions About Suicidal Ideation and Attempted Suicide

### *Suicidal Ideation*

Have you EVER had thoughts of taking your life, even if you would not really do it?

During the PAST 12 MONTHS have you had such thoughts?

Have you EVER thought about specific ways to take your life even if you would not really do it?

During the PAST 12 MONTHS have you thought about specific ways that you could take your own life?

### *Attempted Suicide*

Have you EVER made an attempt to take your own life?

During the PAST 12 MONTHS have you made an attempt to take your own life?

If "yes" to one of above:

Have you suffered an injury or illness as a result of trying to take your own life?

Did you go to a doctor, emergency room, or other health facility for the resulting injury or illness?

Were you admitted to a hospital to stay overnight or longer as a result of trying to take your own life?

# The Relationship Between Adolescent Suicidal Behavior and Life Events in Childhood and Adolescence

Erik J. de Wilde, M.Sc., Ineke C.W.M. Kienhorst, Ph.D.,
René F.W. Diekstra, Ph.D., and Willem H.G. Wolters, Ph.D.

Objective: *Although the relationship between experience of problematic life events and adolescent suicidal behavior has frequently been recognized during the past decade, few studies of life events have been initiated that discriminated between adolescent suicide attempters and depressed adolescents. Therefore, the authors compared adolescent suicide attempters with both depressed and nondepressed adolescents who never attempted suicide with respect to life events that happened in two periods: childhood (defined as the period up to age 12 years) and adolescence (age 12 and older).* Method: *Using a semistructured interview, the authors gathered life event data about childhood and adolescence from three groups of adolescents: 48 suicide attempters, 66 depressed adolescents who had never made a suicide attempt, and 43 nondepressed adolescents who had never made a suicide attempt.* Results: *The group of adolescents who attempted suicide differed from both of the other groups in that they had experienced more turmoil in their families, starting in childhood and not stabilizing during adolescence. During adolescence, they were more often sexually abused. During the last year before the attempt, further social instability, such as changes in residence and having to repeat a class, occurred.* Conclusions: *For suicidal adolescents, the suicide attempt seems embedded not just in the problems every adolescent has to deal with but in greater turmoil in their families, rooted in childhood and not stabilizing during adolescence, in combination with traumatic events during adolescence and social instability in the year preceding the attempt.*

(Am J Psychiatry 1992; 149:45–51)

In their impressive review of attempted suicide in adolescence, Spirito et al. (1) stated, "Presence of stressful life events . . . seems to have important implications for understanding suicide attempts in children and adolescents." Nevertheless, although the relationship between experience of problematic life events and adolescent suicidal behavior has frequently been recognized during the past decade (2, 3), few studies of life events have been initiated that discriminated between adolescent suicide attempters and depressed adolescents. This comparison is essential because many life events that take place in the lives of suicide attempters are also found in the lives of adolescents who report depressed mood (4), which implies that not taking depression into account is problematic when identifying life events specific for adolescent suicide attempters.

Several studies compared suicidal adolescents with heterogeneous psychiatric groups of nonsuicidal adolescents (5–7) or with other clinical groups (8, 9). However, it is not clear from these studies whether the compared groups were depressed or not.

Two studies (10, 11), however, made comparisons using depressed groups. Friedman et al. (10) compared suicidal depressed adolescents with nonsuicidal depressed adolescents but restricted their research to family history of illness. Chronic psychiatric illness of a parent (especially depression) was more frequently found among suicide attempters. Cohen-Sandler et al. (11) compared suicidal children and young adolescents (5–14 years old) with depressed and other psychiatric control groups regarding life events during different developmental periods. They found that more life events were related to suicidal behavior with increasing age.

If the results of Cohen-Sandler et al. were also applicable to adolescents, they would agree with those of

Jacobs (12), who compared 50 adolescent suicide attempters with matched control subjects from schools. He hypothesized that 1) the first of four phases leading to a suicide attempt consists of a longstanding history of problems from childhood to the onset of adolescence and 2) the second phase is a period of "escalation of problems" at the onset of adolescence in excess of those "normally" associated with adolescence (p. 64).

In our opinion, Jacobs failed to find adequate support for his valuable hypotheses because his data analysis was rather obscure and because, by comparing suicidal adolescents with normal adolescents, he did not account for depression. A comparison of suicide attempters with both depressed and "normal" adolescents (as a baseline for "normal" adolescent turmoil) may give more solid information about his hypotheses.

In addition, analysis of Jacobs' hypotheses requires the specification of the period (childhood or adolescence) during which life events have taken place. Therefore, the present study compared adolescent suicide attempters with both depressed and nondepressed adolescents who never attempted suicide with respect to life events that happened in two periods: childhood (defined as the period up to age 12) and adolescence (age 12 and older). Moreover, because of the growing evidence about the importance of recent life events regarding suicide attempts and psychiatric disorder in young people (11, 13, 14), the last year before the attempt (for the suicide attempters) or before the interview (for the other groups) was studied separately.

## METHOD

### *Subjects*

Three groups of subjects were asked to cooperate with this study. The first group comprised 41 girls and seven boys 14–21 years old (mean±SD age=17.5±1.5 years) who attempted suicide 1–52 weeks before the measurement date. The second group consisted of 52 girls and 14 boys 14–21 years old (mean=17.9±1.6) who suffered from a depressed mood at the time of assessment and had never attempted suicide. (For reasons of readability, the adolescents who suffered from a depressed mood will be referred to as "depressed adolescents" in the remainder of the text.) The third group comprised 31 girls and 12 boys 14–21 years old (mean=17.5±1.3), randomly selected from a "normal" school population. The three groups were not matched, but there were no significant differences among them in relevant sociodemographic features such as age (F=1.45, df=2, 154, p=0.24), sex ($\chi^2$=2.43, df=2, p=0.30), and current type of school ($\chi^2$=7.22, df=6, p=0.12).

Two methods were used to recruit subjects for this study. First, institutions for mental health care were asked for referrals, and, second, 9,393 secondary school students were screened (15). Approximately half of the suicide attempters and half of the depressed adolescents were recruited through the institutions of mental health care. The rest of the suicide attempters and depressed adolescents as well as the entire group of normal adolescents were recruited from among the 9,393 secondary school students. The suicide attempters and the depressed adolescents did not differ significantly in this recruitment procedure ($\chi^2$=3.1, df=2, p=0.08).

The study was performed in compliance with the U.S. Human Subject Research Guidelines. Informed consent was obtained from all subjects and their parents.

Almost two-thirds of the suicide attempters had taken an overdose of medicine or toxic substances, one-quarter had injured themselves, and the rest had thrown themselves in front of a moving vehicle, tried to hang themselves, or jumped from a height. The mean±SD score of the suicide attempters on the Suicide Intent Scale (16), 6.8±3.4, was comparable to that of 50 British adolescents who attempted suicide (2). Three suicide attempters had scores of 13, indicative of a strong suicide intent. The mean risk score of all 48 suicide attempters on the Risk-Rescue Rating (17) was 8.1±2.1, indicative of a moderately low risk, and their rescue score on this scale was 11.6±2.3, indicative of a moderately high rescue level.

The 66 depressed adolescents were tested for depression at two separate times. First, at the time of the screening procedure preceding the interview, they were selected randomly if they appeared to have a score of 46 or higher on the Zung Self-Rating Depression Scale (18) and had a score of at least 16 on the Depression Adjective Checklist (19). The depressed adolescents referred from the institutions of mental health care met Research Diagnostic Criteria (20) for major depressive disorder. The second assessment took place at the time of the interview. Subjects who had a score of 46 or higher on the Zung scale at that time were included in this study. Their mean score on the Zung scale was 51.9±5.2, compared with 49.4±11.7 for the suicide attempters and 33.5±5.6 for the normal subjects.

For the normal comparison group, 45 students were initially selected at random for interview from among the secondary school students screened. The criteria for selection were that these students reported they had never made a suicide attempt and that they did not score higher than 46 on the Zung scale or 16 on the Depression Adjective Checklist. Nevertheless, at the time of the interview, two students met the criteria for depression and were removed from the study, leaving 43 adolescents in the normal comparison group.

### *Measures and Data Analysis*

A semistructured interview including several self-report questionnaires was conducted with each subject by a graduate psychology student or a psychologist who was especially trained for this purpose. Before the actual data collection, a pilot study was carried out with eight adolescents; the interview was modified on the basis of the findings of this pilot study.

The Life Event Time Schedule, a part of the Life History Interview (4), was developed for this study. The

[a] $p<0.05$; significant difference between suicide attempters and depressed adolescents (Tukey honestly significant difference procedure).

[b] $p<0.05$; significant difference between suicide attempters and normal adolescents (Tukey honestly significant difference procedure).

[c] $p<0.05$; significant difference between suicide attempters and both depressed and normal adolescents (Tukey honestly significant difference procedure).

main objective of this instrument is to assess the occurrence of life events as well as when they took place. The Life Event Time Schedule consists of 77 items, chosen for their known importance regarding suicidal behavior. Nineteen of these items were examined for this study: serious illness, accident, change in living situation (for example, a change from living with one's biological family to living with a foster family), change in caretaker (for example, from two biological parents to one), separation of parents (parents living apart or divorced), reunion of parents, change of residence, death of a family member, events concerning the physical health of a family member (serious illness, hospital admission, becoming an invalid), events concerning the mental health of a family member (psychiatric hospital admission, nervous breakdown, contact with mental health institute), unemployment of a family member, imprisonment of a family member, sibling leaving home, change of school or type of school, repeating a class, ending a relationship, physical abuse, sexual abuse, and criminal events (breaking the law, prosecution, fine, or imprisonment). Because our primary interest lay in the occurrence of specific events, no effort was made to assign weights to the individual items.

The number of events reported was analyzed separately for three time periods—up to 12 years of age, from 12 years of age until the date of suicide attempt or the date of the interview, and the last year before the suicide attempt or date of interview. Univariate comparisons were made with the Kruskal-Wallis nonparametric analysis of variance (21). The distribution of the attained statistic, H, which was corrected for ties, is approximated by chi-square. To determine which groups were different from each other, a Tukey honestly significant difference procedure (22) was performed whenever H reached significance. In addition, for significant differences the percentage of subjects in each group who experienced the event in a given period is described in the text. This indicates the person-rate frequency of the events, as opposed to the event-rate data given in the tables.

## RESULTS

Table 1 shows the results for the period of childhood. These results indicate that suicide attempters differed from depressed adolescents in that they experienced more events of separation of their parents before the age of 12. This occurred in 11 (23%) of the suicide attempters, compared with four (6%) of the depressed adolescents and four (9%) of the normal adolescents. Suicide attempters also differed from normal adolescents in that they reported more events of physical abuse before the age of 12 than did normal adolescents. Seven (15%) of the suicide attempters, seven (11%) of the depressed adolescents, and none of the normal adolescents reported physical abuse in childhood. Besides these significant differences, suicide attempters experienced more problematic life events during childhood than did depressed and normal adolescents; this is indicated by the total number of events (table 1).

**TABLE 2. Number of Major Life Events Experienced During Adolescence (Age 12 and Later) by Adolescents Who Attempted Suicide, Depressed Adolescents, and Normal Adolescents**

| Total number of events | 10.92 | 5.41 | 9.41 | 4.15 | 7.65 | 3.65 | 9.47[d] |

[a] $p<0.001$; significant difference between suicide attempters and both depressed and normal adolescents (Tukey honestly significant difference procedure).

[b] $p<0.01$; significant difference between suicide attempters and both depressed and normal adolescents (Tukey honestly significant difference procedure).

[c] $p<0.05$; significant difference between depressed and normal adolescents (Tukey honestly significant difference procedure).

[d] $p<0.01$; significant difference between suicide attempters and normal adolescents (Tukey honestly significant difference procedure).

There were more differences among the three groups from the age of 12 on (table 2). Suicide attempters differed from depressed and normal adolescents in that they experienced more changes in living situation and in caretaker as well as parental divorce or separation (of course, these variables are correlated). Twenty-one (44%) of the suicide attempters experienced changes in living situation, compared with 12 (18%) of the depressed adolescents and two (5%) of the normal adolescents. Eighteen (38%) of the suicide attempters reported changes in caretaker, compared with nine (14%) of the depressed adolescents and five (12%) of the normal adolescents. Thirteen (27%) of the suicide attempters experienced parental separation, compared with seven (11%) of the depressed adolescents and two (5%) of the normal adolescents. Suicide attempters differed from normal adolescents in that they reported more sexual abuse. Sixteen (33%) of the suicide attempters reported sexual abuse during adolescence, compared with 14 (21%) of the depressed adolescents and two (5%) of the normal adolescents. The suicide attempters reported a significantly higher number of total events than did normal adolescents (table 2).

Depressed adolescents reported more physical abuse during adolescence than did normal adolescents (table 2). Nineteen (29%) of the depressed adolescents reported physical abuse during adolescence, compared with 11 (23%) of the suicide attempters and three (7%) of the normal adolescents.

Table 3 shows the mean number of events reported by the subjects as happening in the year preceding the suicide attempt or the year preceding the interview. Suicide attempters experienced more changes in living situation and caretaker and more repetitions of a class than both other groups. Thirteen (27%) of the suicide attempters reported changes in living situation during the last year, compared with four (6%) of the depressed adolescents and none of the normal adolescents. Six (13%) suicide attempters, compared with one (2%) depressed adolescent and none of the normal adolescents, reported changes in caretaker. Five (10%) suicide attempters, compared with one (2%) depressed adolescent and none of the normal adolescents, reported repeating a class. Five (10%) suicide attempters, compared with two (3%) depressed adolescents and none of the normal adolescents, reported separation of parents. Six (13%) suicide attempters, compared with four (6%) depressed adolescents and none of the normal adolescents, reported changes of residence. Nine (19%) suicide attempters, compared with nine (14%) depressed adolescents and one (2%) normal adolescent, reported mental health events involving family members. Five (10%) suicide attempters, compared with two (3%) depressed adolescents and none of the normal adolescents, reported sexual abuse. The suicide attempters reported a higher mean number of total events than the depressed and normal adolescents (table 3).

Depressed adolescents differed from both other groups in that they reported more physical health events of family members during the preceding year.

[e] $p<0.05$; significant difference between suicide attempters and both depressed and normal adolescents (Tukey honestly significant difference procedure).

Sixteen (24%) of the depressed adolescents reported such an event, compared with two (4%) of the suicide attempters and two (5%) of the normal adolescents.

## DISCUSSION

This study compared adolescent suicide attempters with both depressed and nondepressed adolescents who never made a suicide attempt with respect to the occurrence of life events during childhood, during adolescence, and during the year before the attempt or the year before the date of the interview. In all three time periods, suicide attempters reported more negative life events than did "normal" adolescents. Suicide attempters also reported more negative life events, especially in childhood and during the preceding year, than did depressed adolescents. The overall differences among groups in life events during childhood became larger during adolescence and still larger during the year before the attempt or interview.

In this respect our study seems to confirm the two cited hypotheses of Jacobs (12), who compared adolescent suicide attempters with normal matched control subjects. Our study seems to confirm Jacobs' hypothesis that suicide attempters have a longstanding history of problems during childhood and adds the evidence that this is true not only when suicide attempters are compared with normal subjects but also when they are compared with depressed adolescents. This suggests that the risk of suicide during adolescence might be detected during childhood.

In our comparison of suicide attempters with normal adolescents during adolescence and during the preceding year, our study confirms Jacobs' suggestion that suicidal adolescents experience a period of escalation of problems starting at the onset of puberty. With respect to life events in adolescence, however, our group of depressed adolescents were "in the middle" of the other two groups. During the preceding year, our suicide attempters experienced considerably more problematic life events than did both depressed and normal adolescents.

These results stand for the person-rate frequencies as well as the event-rate frequencies, excluding the possibility that certain statistics may be blurred by the fact that a few individuals in one group experienced an excessive amount of life events. Looking at the type of events, one can observe that suicide attempters suffered from more turmoil in family life during all three time periods. In childhood this was characterized by separation or divorce of parents and unemployment of family members. Under these unstable familial circumstances, characterized by immoderate changes in living situation and caretaker during adolescence, the suicide attempter was characterized by more periods of sexual abuse.

During the last year before the attempt, further social instability—changes in residence and repetition of a class—occurred.

Regarding the finding that adolescent suicide attempters experienced more sexual abuse during adolescence, an extra remark may be appropriate. Our findings, plus those of Deykin et al. (8), suggest that sexual abuse is an important field of attention when dealing with adolescent suicide attempters.

To make a correct estimation of the value of our findings, methodological remarks should be kept in mind. For pragmatic reasons, studying a reasonably large group of adolescent suicide attempters almost requires the use of a retrospective method to investigate changes during childhood. Comments suggest that making use of semistructured interviews may be better than using self-report questionnaires (23) and that predefined events may be more reliable than open-ended questions requiring spontaneous recall. In the present study, both preferable choices were made. In addition, each reported event was discussed in reasonable detail: the interviewer asked when exactly did the event happen, how long did it last, who was involved, etc. This procedure, too, may very well increase reliability. However, adolescents who recently attempted suicide may have a different recollection of various life events, influenced by their mood, for example (24). Apart from the fact that this may apply to depressed adolescents as well, we think it unlikely that children easily forget events such as parental separation or divorce or repetition of a class.

Another possible critique was formulated by Brown (25), who described "retrospective contamination," which for this study suggests that the suicide attempters reported more problematic life events to account for their attempt. In the present study, this might have been the case for the suicide attempters as well as the depressed adolescents, who might have reported more events to account for their depressed mood.

The life events considered here were not studied as causes for suicidal behavior. They are possibly interrelated: one event may lead to another, and they may cluster and have additive effects. For example, the divorce of parents may be related to changes in living situation and caretaker and may precede the reunion of parents. Moreover, this study focused on the importance of life events alone regarding suicidal behavior. Of course, this implies a considerable simplification of processes that adolescents in general and suicidal adolescents particularly go through during childhood and adolescence. For instance, the present study did not investigate any constitutional or neurobiological factors. In addition, psychological variables, which probably have great importance in suicidal behavior (1, 15, 26), were not investigated here. This should be kept in mind when assessing the importance of life events in suicidal behavior.

In spite of these methodological questions, we conclude from these results that adolescent suicide attempters are different from both normal and depressed adolescents with regard to life events. The suicide attempt seems embedded in a situation of not just the problems every adolescent has to deal with but turmoil in family life, already rooted in childhood and not stabilizing during adolescence, in combination with traumatic events during the period of adolescence and social instability in the year preceding the attempt.

# Psychiatric Correlates of Incest in Childhood

Elizabeth F. Pribor, M.D., and Stephen H. Dinwiddie, M.D.

*Objective: The purpose of the study was to describe more precisely the type of psychiatric illness associated with incest during childhood. Method: The Diagnostic Interview Schedule was administered to 52 adult women who had been victims of incest during childhood and to 23 age- and race-matched comparison subjects from local self-help agencies. Results: The prevalence of 19 psychiatric disorders was higher in the incest group than base population rates. Rates of anxiety disorders (panic disorder, agoraphobia, social and simple phobia), major depression, and alcohol abuse and dependence were significantly higher in the incest group than in the comparison group. More severe types of incestuous abuse were associated with a higher risk for the development of psychiatric disorders. Conclusions: There was an association between incest and psychiatric disorders in this community-based treatment population. All patients, especially those who present with these specific psychiatric disorders, should be queried about childhood sexual abuse during the history.*

(Am J Psychiatry 1992; 149:52–56)

In recent years, literature about child sexual abuse has proliferated. Despite its growing recognition, however, many aspects of child sexual abuse remain poorly understood. Specifically, very little is known about the long-term psychiatric outcome of victims of child sexual abuse in general, and incest in particular.

While the definition of incest is not consistent, for our purposes the medical definition "sexual intercourse or other sexual activity between persons so closely related that marriage between them is legally or culturally prohibited" (1) is most accurate. This includes sexual contact such as fondling of the breasts, buttocks, or vagina, cunnilingus, fellatio, and vaginal or anal intercourse.

Because of its social stigma, the incidence and prevalence of incest have been difficult to measure, in part because of different definitions of abuse and variable makeup of the samples studied. Finkelhor (2), in his survey of 796 college students, found a 28% prevalence of incest (defined as "a sexual experience with a family member") in college women. Half of that was incestuous contact between siblings; of that number, 30% of the sibling incest involved force and was considered exploitative. Twenty-three percent of the sibling incest was perpetrated by siblings 5 or more years older and was also considered exploitative. Thus, approximately 18%–19% of these college women reported exploitative incestuous contact before age 18.

In what is probably the best designed study of the prevalence of incest, Russell (3) interviewed 930 women from a random sample of San Francisco households, finding that 38% had been sexually abused by an adult before the age of 18. Of those, 16% of the total sample (N=152) had been victims of exploitative incest.

Specific information about the psychiatric sequelae of incest is sparse. Finkelhor (4) noted significantly lower levels of sexual self-esteem in both men and women who had been victims of sexual abuse as children, although the nature of the problems these individuals had was not described. Similarly, Herman et al. (5), studying 205 adult women with histories of incest, found that 50.4% believed that the abuse had had significant, long-lasting, negative effects in their lives, while 77.6% noted some long-lasting negative effects. Of the 152 women who had been victims of incest in Russell's survey (3), 53% described the incestuous experience as extremely or very upsetting, and an additional 27% found it somewhat upsetting. Russell concluded that 34% of the victims had experienced extreme trauma, 23% considerable trauma, and 25% some trauma.

Gelinas (6) found three major areas of difficulty among incest victims: "chronic traumatic neuroses, continuing relational imbalances and increased intergenerational risk of incest." Browne and Finkelhor's literature review (7) summarized the long-term effects of childhood sexual abuse including symptoms of depression, anxiety, and substance abuse; self-destructive behavior including suicide attempts; and sexual maladjustment.

Stein et al. (8), using data from the Los Angeles site of the National Institute of Mental Health (NIMH) Epidemiologic Catchment Area (ECA) study, reported a 6.8% prevalence of childhood sexual abuse in women, well below other estimates. Among the 51 women in the sample who had been victims of child sexual abuse, Stein et al. found a higher prevalence of alcohol abuse and dependence, drug abuse and dependence, major depressive disorder, and phobias. Nearly 60% of the women had at least one diagnosis.

Some authors have reported a correlation between childhood sexual abuse and the development of dissociative disorders. Putnam et al. (9) found that 97% of patients with multiple personality disorder had histories of abuse during childhood. Ross et al. (10) reported that 74.4% of 207 female patients with multiple personality disorder had histories of childhood sexual abuse.

There is also evidence that long-term effects may be influenced by the type of abuse sustained by the victim. Russell (3) demonstrated that more severe forms of sexual abuse produced higher levels of trauma than did fondling or kissing, and both Finkelhor (4) and Russell (3) reported a worse outcome when physical force had been involved. However, the relationship between more traumatic forms of sexual abuse and later development of specific psychiatric syndromes is unknown.

## METHOD

One of us (E.F.P.) contacted all centers in the St. Louis area with specialized programs for sexually abused women, including family service agencies and self-help groups. A psychologist and two social workers known locally to work with sexually abused women were contacted as well. Therapists who agreed to participate in the study agreed that all individuals in therapy would be informed of this study and given the opportunity to participate. In one community-based self-help group run entirely by the participants, one of us (E.F.P.) met with the group, presented information about incest, and offered all group members the opportunity to participate.

All potential subjects were mailed information about the structure and purpose of the research project and were asked to participate. Those who replied were contacted by phone, and interviews were scheduled. Informed consent was obtained before the interview, for which there was no financial remuneration.

Overall, 64% of the subjects who were asked agreed to participate. This rate varied among the individual referral sources, ranging from 43% to 100%. Ninety-three percent of the individuals who agreed to participate were ultimately interviewed. Comparison subjects were age- and race-matched women with no history of physical or sexual abuse and were drawn from the same sources. The consent rate for the comparison subjects was 48%; 89% of those who responded were interviewed. The consent rates did not differ significantly between comparison subjects and incest victims ($\chi^2$=2.88, df=1, n.s.).

**TABLE 1. Abuse Reported by Incest Victims (N=52)**

| Abuse | N[a] | % |
|---|---|---|
| Fondling | 50 | 96.2 |
| Cunnilingus | 18 | 34.6 |
| Fellatio | 19 | 36.5 |
| Sexual intercourse | 19 | 36.5 |
| Unsuccessful attempt at sexual intercourse | 3 | 5.8 |
| Anal intercourse | 6 | 11.5 |
| Pictures[b] | 3 | 5.8 |
| Group sex | 7 | 13.5 |
| Other sexual activity | 4 | 7.7 |

[a] Total is greater than 100% since many subjects reported more than one form of abuse.

[b] Taking sexual pictures or movies of the girl or forcing her to watch pornography.

The final study population included 52 women who had been victims of incest and 23 comparison subjects. Of the incest subjects, 44 (84.6%) were Caucasian, seven (13.5%) were black, and one (1.9%) was Hispanic. The mean±SD age was 36.9±7.0 years. Of the comparison subjects, 21 (91.3%) were Caucasian and two (8.7%) were black. The mean age was 35.9±9.2 years.

For the purpose of this study, incest was defined as unwanted sexual contact between the interviewee and a relative too close to marry, thus excluding so-called mutual exploration between siblings or other peers and inappropriate sexual activity that did not include sexual contact, such as exposure and sexually explicit comments, suggestions, or proposals. This definition did not specify a necessary age difference between the victim and the perpetrator.

All subjects were given a computerized version of the NIMH Diagnostic Interview Schedule (DIS) (11, 12), a structured interview based on *DSM-III* that has been proven to be at least as reliable as individual examinations by psychiatrists in clinical samples (13). Subjects were also asked a set of questions about the incestuous event or events, other sexual abuse, and past use of mental health services.

## RESULTS

The types of abuse reported are listed in table 1. The average number of offenders per victim was 1.8±1.5 (range=1–7, mode=1). The average age at the onset of incest was 6.5±3.3 years. The perpetrator was reported to an authority in seven instances (13.5%); physical force was involved with some of the abuse in 16 cases (30.8%). A history of physical abuse unrelated to the incest, not necessarily by the incestuous abuser, was reported by 31 women (59.6%). Finally, nonincestuous sexual abuse during either adulthood or childhood was reported by 24 of the women (46.2%).

Of 26 possible diagnoses listed in table 2 (with alcohol abuse, alcohol dependence, substance abuse, and

[e] $p<0.05$.
[f] $p<0.01$.

substance dependence representing four separate diagnoses), the average number of lifetime diagnoses was 7.1±2.3 (range=1–16, mode=5) for the incest victims versus 3.2±3.4 (range=0–9, modes=2, 3, 7) for the comparison subjects. Excluding tobacco dependence, the average number of diagnoses were 6.7±3.4 (range=1–15, mode=5) and 2.8±2.7 (range=0–8, modes=3, 6) for the victims and comparison subjects, respectively (Wilcoxin rank sum, Z=–2.23, p=0.03).

Compared with the lifetime prevalence rates for a comparable group of women aged 18–55 in the St. Louis ECA study, the incest victims had markedly higher lifetime prevalence of most major psychiatric disorders (table 2). In order to allow comparison to the ECA data, alcohol and substance abuse and dependence were combined to make a total of 24 tested diagnoses. The prevalence of bulimia (not tested in the St. Louis ECA study) was also higher than expected rates (14, 15).

The differences in the prevalence of psychiatric disorders were less pronounced when incest victims were compared with other study subjects derived from treatment samples. Nonetheless, incest victims demonstrated a substantially higher lifetime prevalence of agoraphobia, alcohol abuse or dependence, depression, panic disorder, posttraumatic stress disorder (PTSD), simple phobia, and social phobia (table 2). The likelihood of having any psychiatric diagnosis was significantly higher for incest victims than for comparison subjects ($\chi^2$=4.08, df=1, p=0.04).

Among incest victims, those subjected to vaginal intercourse had higher rates of agoraphobia ($\chi^2$=8.73, df=1, p<0.01), simple phobia ($\chi^2$=11.94, df=1, p<0.001), panic disorder ($\chi^2$=11.05, df=1, p<0.001), PTSD ($\chi^2$=8.94, df=1, p<0.005), and somatization disorder ($\chi^2$=6.16, df=1, p<0.05). In cases in which physical force had been used, the victims had a higher prevalence of obsessive-compulsive disorder ($\chi^2$=4.70, df=1, p<0.05), simple phobia ($\chi^2$=7.31, df=1, p<0.01), somatization disorder ($\chi^2$=4.27, df=1, p<0.05), and PTSD ($\chi^2$=7.31, df=1, p<0.01).

Of the 52 incest victims interviewed, 41 (78.8%) had seen at least one mental health professional before their present therapist or group. Of these, 34 (82.9%) felt that their prior therapist had not been helpful. Twenty-eight (53.8%) had never seen a psychiatrist, while 21 (40.4%) stated that they had seen a psychiatrist but did not find him or her to be helpful with their psychiatric problems. Only three (5.8%) stated that they had been treated by a psychiatrist who they felt had been helpful.

## DISCUSSION

As expected, compared to general population rates, women in treatment who had a history of incestuous abuse in childhood reported higher prevalence of virtually every psychiatric disorder investigated other than anorexia nervosa, mania, pathological gambling, and schizophrenia. Much of the higher rate could be attributed to sampling from a treatment population; however, even when compared to age- and race-matched treated comparison subjects, incest victims still demonstrated higher rates of anxiety disorders (agoraphobia, panic disorder, PTSD, and phobias), depression, and alcohol abuse and dependence.

Incest victims also had a significantly higher *number* of diagnoses than did comparison subjects, demonstrating a pattern of greater liability to illness. Since multiple comparisons were made on the same population, it is likely that some of these findings are due to chance. However, the validity of these findings is supported by the results of Stein et al. (8), who found a similar pattern of diagnoses in their sample drawn from a community survey. Our results diverged from those of Stein and co-workers only in that a higher rate of panic disorder was found in the present study, and in the prior study the prevalences of agoraphobia and PTSD were not reported. Absolute rates for the remaining disorders were higher in the St. Louis sample, probably because of differences in recruitment of subjects.

Other studies have indicated that dissociative disorders also may be associated with sexual abuse in childhood. Using the Dissociative Emotive Scale, Bernstein and Putnam (16) reported a correlation between elevated scores and presence of severe dissociative disorders, including multiple personality disorder; this finding was replicated by Ross et al. (17). Similarly, Chu and Dill (18) found that in female psychiatric inpatients, a history of sexual abuse by family members was associated with elevated scores on the Dissociative Emotive Scale, although much of this finding appeared to be accounted for by concomitant physical abuse. Interestingly, in that study, elevated scores on the Dissociative Emotive Scale did not correlate with the clinical diagnosis of a dissociative disorder or PTSD. Because the DIS does not diagnose dissociative disorders, the question of their prevalence in our population must be left unanswered. Future studies of outpatient samples should consider the use of the Dissociative Emotive Scale or similar instrument in order to test the association between childhood sexual abuse and prevalence of dissociative disorders in adulthood. In our population, certain psychiatric disorders were strongly associated with more severe forms of sexual abuse such as intercourse or use of physical force. This finding is consistent with the reports of Russell (3) and Finkelhor (2, 4), who reported greater measures of distress in women who reported more severe forms of abuse.

The incest victims in our group were unlikely to perceive benefit from mental health services in general. Half reported that they had never seen a psychiatrist; of those who had, almost none indicated that they found the experience beneficial. Many of the women volunteered that they had never told their psychiatrists about the abuse, nor were they ever asked. This outcome is made more disturbing by the fact that, excluding tobacco dependence, all subjects had at least one psychiatric disorder and on average met criteria for seven on a lifetime basis. Given the high rates of anxiety disorders and depression, potentially treatable by pharmacotherapy or a combination of psychotherapy and pharmacotherapy, psychiatric intervention might be of unique benefit in this population.

Certain limitations of this study must be kept in mind. First, this was a treatment population, not a random sample of incest victims. However, most of the subjects did not initially approach the agencies from which they were referred with a complaint of having been abused. Instead, the vast majority sought help for psychiatric symptoms or interpersonal problems. Although prior community survey literature does not indicate the percentage of incestuously abused women who have sought help from mental health professionals, this population may overlap with the 57% to 82% who experienced significant trauma as determined in Russell's work (3) or the 50% to 78% of Herman and associates' sample (5) who complained of long-lasting negative effects.

While this study shows an association between incest and psychiatric disorders, it does not explain it. One possibility is that there is a direct causal relationship with incest resulting in trauma which leads to psychiatric problems (including symptoms of depression, anxiety, and poor interpersonal relationships), which in turn bring the individual to treatment. Alternatively, incest could be viewed as a marker for a severely dysfunctional family. It may be that the dysfunctional family environment rather than the incestuous act per se plays a major role in the genesis of interpersonal problems leading to the development of psychiatric symptoms and disorders. In addition, some psychiatric disorders are familial, and the degree of psychiatric illness in the victims' families is unknown.

It could be argued that our study either overestimates or underestimates the true prevalence of psychiatric disorders among incest victims. Because this was a treatment population, victims without any psychiatric distress would have been missed. On the other hand, because we did not include hospitalized inpatients and patients of psychiatrists, the more disordered victims might have been underrepresented. On balance, our population represents women who are troubled and have brought themselves to treatment. Thus, this population focuses on those women who are most likely to both need and seek help.

This study demonstrates a higher prevalence of psychiatric problems in women with more severe types of abuse. It also shows that many victims feel they had not been helped by their psychiatrists or other therapists, perhaps because incest was rarely asked about. Nonetheless, the victims have many potentially treatable psychiatric illnesses. We recommend that childhood sexual abuse be asked about in the initial history, and clinicians should consider repeating this inquiry later, after a therapeutic alliance has been firmly established. To best explicate causal factors of psychiatric illness in incest victims, future research should include large patient samples, be community based, and attempt to ascertain the proportion of women who ever seek help from professionals.

# Congenital Malformations and Structural Developmental Anomalies in Groups at High Risk for Psychosis

Thomas F. McNeil, Ph.D., Gösta Blennow, M.D., Ph.D., and Louise Lundberg, M.D.

---

*Objective: Early somatic developmental anomalies may be one expression of a genetic influence toward psychosis. The purpose of this study was to investigate whether higher rates of early developmental anomalies are associated with heightened genetic risk for psychosis. Method: Rates of congenital malformations and minor structural developmental anomalies were prospectively investigated in 84 high-risk offspring of women with histories of psychosis of nonorganic origin (schizophrenic, schizoaffective, affective, and other psychoses) and in 100 offspring of demographically similar control women with no history of psychosis. Data were collected by means of multiple physical examinations through the first 3–4 years of the offspring's lives. Results: The rates of total congenital malformations were high, but the great majority of these malformations in both the index group and the control group represented minor physical aberrations. Rates of congenital malformations in the offspring of the index women (or any specific diagnostic subgroup of these women) were not different from those in the offspring of the control women. Conclusions: The inferred genetic risk for psychosis does not appear to be associated with greater rates of early somatic developmental anomalies, suggesting that early developmental anomalies do not represent an expression of genetic influence toward psychosis.*

(Am J Psychiatry 1992; 149:57–61)

---

Evidence suggests increasingly that somatic trauma to the fetus and/or maldevelopment of the offspring during pregnancy or the perinatal period are in some manner associated with the development of psychosis in the same offspring in adulthood (1–6). The relation between early trauma/maldevelopment and later psychosis appears to involve primarily schizophrenia, but some data also suggest an association with schizoaffective (6) and bipolar affective (2) disorders. The specific role of maternal obstetric complications in the development of schizophrenia and other psychoses in the offspring, as well as the relation between obstetric complications and genetic factors, remains to be determined. Perhaps the most likely interpretation of the greater rates of maternal obstetric complications or early developmental anomalies among prepsychotic offspring is that these phenomena represent early fetal trauma, with neurobiological consequences which contribute to the later development of psychosis. An alternative interpretation is that the obstetric complications or developmental anomalies are merely an expression of genetic influence (7–10) or a secondary correlate of other parental environmental influences (4). If the latter were true, obstetric complications would be an epiphenomenon (i.e., a consequence or correlate of psychosis) rather than a primary "somatic trauma" factor contributing to the development of psychosis.

One strategy available at present for investigating the hypothesis that early trauma/developmental anomalies are a direct or indirect expression of genetic influence toward psychosis is to study the rate of early trauma and developmental anomalies in groups of individuals at greater genetic (and perhaps environmental) risk for the psychiatric disorders of interest (11). Numerous such studies have been done regarding maternal obstetric complications, and the extensive evidence obtained to date indicates clearly that pregnancy and birth complications of the type typically registered by prenatal and obstetric services do *not* occur unusually frequently among offspring who are at greater genetic risk for psychoses (4–6, 12). This suggests that neither genetic factors nor the many other possible environmental factors directly associated with parental psychosis influence the occurrence of obstetric complications of the type related to risk for schizophrenia in offspring. Thus, obstetric complications do not appear to represent an epiphenomenon.

In contrast, there appears to be little empirical evi-

dence concerning whether congenital malformations, including minor structural developmental anomalies, occur unusually frequently among individuals at heightened genetic (and environmental) risk for psychosis. To our knowledge, only three studies have systematically investigated the rates of congenital malformations in the offspring of parents with psychosis. Sobel (13) used psychiatric records to investigate rates of malformations occurring in 222 offspring of schizophrenic women who were in New York state mental hospitals at the time of delivery in 1950–1958. He reported a higher rate of malformations in these offspring (3.2%) than in two separate samples from the general population (about 1%). Similarly, Rieder et al. (14) found that there were significantly more deaths associated with neurological malformations among offspring of parents with various psychiatric illnesses (1.9%) than among offspring of control parents (0%). In contrast, Paffenbarger (15) found no difference in rates of congenital defects between the offspring of 126 women with postpartum psychosis and the offspring of control women (no specific rates of congenital malformations were given for either group). Reports from two other studies (16, 17) included mention of several specific congenital malformations found among the offspring of schizophrenic parents, but no group rates of congenital malformation per se were cited for the samples. The greater frequencies of congenital malformations in high-risk offspring reported in the studies by Sobel and Rieder et al. were thus associated with rather severe conditions (childbirth in mental hospitals, congenital malformations associated with death of the offspring) and represented rather minimal increases in the rates of these malformations (2%–3%) as compared with low control group rates (0%–1%).

Furthermore, the studies to date appear to have included only major congenital malformations. Considerable scientific interest has more recently been directed toward congenital aberrations termed "minor physical anomalies." Minor physical anomalies are minor congenital malformations found primarily in the ectoderm (18, 19); they develop during the first trimester of pregnancy as a result of genetic or other teratogenic factors. Minor physical anomalies may represent signs of early developmental anomaly occurring at approximately the same gestational time as major CNS development. Furthermore, since many minor physical anomalies develop in the same embryonic layer as does the CNS, minor physical anomalies might represent an externally visible sign of parallel developmental deviation in the CNS itself (18, 19). Evidence suggests that minor physical anomalies occur with greater frequency among persons with schizophrenia, autism, mental retardation, hyperactive or inhibited behavior, learning difficulties, and speech and hearing difficulties (3, 18–23), thus supporting a coupling of early developmental anomaly and the subsequent development of a range of different mental disorders.

Further study of the rate of both major congenital malformations and minor developmental anomalies among offspring at high risk for psychosis is therefore indicated. Data collected in our prospective study of the offspring of pregnant women with histories of psychosis and the offspring of pregnant control women with no history of psychosis (24) provided the opportunity to investigate this topic in several maternal psychosis groups and demographically similar control groups. The data on congenital malformations were obtained from examinations conducted on numerous occasions during the offspring's first several years of life, thus providing a long-term assessment of somatic developmental anomalies that reflect pre- or perinatal maldevelopment. The hypothesis tested was that the offspring of women with psychosis more frequently have congenital malformations than do the offspring of normal control women.

## METHOD

The index sample consisted of 84 offspring of pregnant women who registered at the comprehensive prenatal clinics in southern Sweden during a 4.5-year sampling period (1973–1977), who had histories of hospitalization for nonorganic psychosis before the current pregnancy, who participated in the longitudinal study (24), and for whose offspring information was available concerning the presence of congenital malformations. Table 1 shows the distribution of the maternal psychiatric diagnoses in the 84 cases according to the Research Diagnostic Criteria (RDC) (25) and the project's own diagnostic criteria (24). Project criteria include schizophrenic, cycloid, affective, and other, "nonendogenous" psychoses. The RDC definitions of schizophrenic disorders and affective disorders (manic, bipolar, and major depressive) are broader than the project criteria for these two types of disorders, and the RDC schizophrenic and affective disorder subjects included all project-criteria schizophrenic and affective disorder subjects, respectively, plus a number of subjects from the project-criteria "other psychoses" group. The use of the two diagnostic systems in parallel provides the opportunity to study the effects of breadth of diagnostic definitions on study results (26, 27).

The control sample consisted of 100 offspring of pregnant women with no history of psychosis who were matched with the women in the index sample with respect to the clinic at which they received prenatal care, maternal parity, age, social class, and marital status during pregnancy; who participated in the longitudinal study (24); and for whose offspring there was information regarding congenital malformations. Each diagnostic group had its own matched control group.

Informed consent was obtained after the procedures had been fully explained. Only one perinatal death (of a control subject) and no postnatal deaths occurred in the samples.

Information concerning congenital malformations in the entire group of 184 offspring was obtained from well-baby clinic records covering repeated physical ex-

aminations during the first 3–4 years of life (28). In addition to these routine pediatric examinations, all but 13 of the infants were also examined by one or more project researchers; the first author examined 154 infants at delivery, and 127 were examined by the second author on the third or fourth day postpartum. In 11 of the 13 cases in which the infant was not seen by a project researcher, information about the child's condition was obtained from clinic personnel at the time of delivery. The current study included systematic evaluation for not only major congenital malformations but also minor congenital malformations and minor physical anomalies such as birthmarks, simian line, sacrococcygeal pits, etc.

All congenital malformations identified through these three sources were classified (by the third author) according to the system of Ekelund et al. (29) as representing variants, minor structural abnormalities, or major congenital malformations; the last were further subdivided into dubious or insignificant type and gross type. In table 1 and in the statistical analyses, if a child had multiple congenital malformations belonging to more than one of these three categories, classification of the child as having major congenital malformations was given priority over classification as having minor congenital malformations or variants, and minor congenital malformations were given priority over variants.

The frequency of offspring having no congenital malformation versus those having some congenital malformation was analyzed statistically for both the total index sample and each diagnostic group and its matched control subjects with the use of chi-square and Fisher's exact probability tests. The hypothesis indicated one-tailed analyses.

## RESULTS

### *Congenital Malformations in the Total Sample of Index Plus Control Offspring*

The rates of total congenital malformations and the frequencies of subjects categorized as having no congenital malformations, variants, minor congenital malformations, and major congenital malformations are shown in table 1. The nature and frequencies of the specific congenital malformations observed in the index group and the control group are shown in table 2.

Among the total 184 offspring, 69 (38%) had at least one congenital malformation, and eight (4%) had two. More than half (58%, N=45) of the total congenital malformations (N=77) in these 184 offspring belonged to the variant category, while 25% (N=19) represented minor congenital malformations, and 17% (N=13) were major congenital malformations. A number of the major malformations identified (positive Ortolani's sign, cardiac murmur, pyloric stenosis) belonged to the subgroup termed "dubious or insignificant" by Ekelund et al. (29), and only a few subjects (2%, N=4 of 184) had major congenital malformations of the gross type (table 2). Among the 18 subjects with minor congenital malformations, one had two different minor malformations and four others also had malformations classified as variants. Three of the 38 subjects with only

variants had two different congenital malformations. All subjects with major congenital malformations had only one malformation each.

### *Congenital Malformations in the Index Versus the Control Offspring*

As shown in table 1, the index and control groups were very similar to each other in rates of total congenital malformations, variants, minor congenital malformations, and major congenital malformations. Division of the sample according to the different maternal psychiatric diagnostic subgroups and their demographically matched control groups yielded quite small subgroups with congenital malformations, but the data suggested that the rates of malformations for the specific diagnostic groups were not notably different from those for their respective control groups. Diagnosis of maternal psychosis according to the RDC versus the project criteria led to no notable differences in rates of congenital malformations among the offspring of mothers with schizophrenic, schizoaffective/cycloid, and affective disorders. Furthermore, the specific types of congenital malformations found in the total index group were well distributed across the different psychiatric diagnostic subgroups. No significant difference was found on any of the statistical comparisons, and the hypothesis of greater rates of congenital malformations in index cases was not supported by the results.

## DISCUSSION

In this prospective study, offspring of women with histories of nonorganic psychosis were found not to differ from offspring of normal control women in rates of congenital malformations classified in several different ways. This absence of index-control differences was not due to an insufficient frequency of congenital malformations in the samples. More than one-third of the offspring in the combined index and control samples had one or more of the broad range of physical deviations classified as congenital malformations, and 7% had major congenital malformations.

The rates of congenital malformations observed in a sample will be influenced by the intensity of scrutiny and examination during a given period, the length of follow-up, and the breadth of physical deviations subsumed within the concept of congenital malformations and developmental anomalies. The very high rate of total congenital malformations observed in both the index and control samples was likely due to all of these factors. 1) A broad range of aberrations was intentionally selected for inclusion among congenital malformations, and indeed a great majority (83%) of the malformations identified were variants or minor structural abnormalities, while only 17% were major classical congenital malformations, and even fewer (5%) were gross major congenital malformations. 2) Congenital malformations were identified through multiple examinations, including extra neonatal physical examinations done for research purposes and with special attention paid to minor deviations. 3) The data reflected a long observation time for the identification of congenital malformations, that is, the first 3–4 years of life; previous studies indicate that the rate of identified malformations doubles if children are followed up through 5 years of age rather than just examined perinatally (30). Furthermore, the possibility that factors which increase the risk of congenital malformations were found in both samples cannot be excluded. For example, both index and control mothers were unusually old at the time of these births (24).

Whatever the reasons for the high total rates of congenital malformations, the identification procedure was applied in a comparable manner to the index and control groups, and the two groups were found not to differ in these rates. Because the rates in the index and control groups did not differ, further possible analyses to determine any relations between these malformations and other factors such as maternal obstetric complications and maternal medication during pregnancy are not indicated, as might have been the case if the index subjects had had higher rates of congenital malformations.

The similar rates of congenital malformations in the index and control groups could be interpreted in several different ways. There could be a relation between greater genetic risk and the occurrence of congenital malformations, but this relationship would not be discernible in the present study because too few of these high-risk offspring would have the gene (or genes) for psychosis. Unfortunately, there is no certain knowledge about the true frequency of psychosis-related genes in the offspring of, for example, one schizophrenic parent (31). Although the true rate of expected gene carriers in our offspring samples cannot be estimated prior to identification of the psychosis-related gene (or genes) or the true genetic mode of inheritance, the frequency of gene carriers could, nevertheless, have well exceeded the rate of expected psychotic cases in these offspring groups (10%–25%) (24). For example, relatively low rates of concordance for schizophrenia have been observed in modern studies of monozygotic twins (32), and these pairs by definition have a genetic makeup that is "sufficient" to permit the development of schizophrenia in at least one of the twins.

Whatever the true rate of gene carriers in the index offspring, an existing relationship between psychosis-related genes and congenital malformations should have led to at least a nominally greater rate of congenital malformations in the index group than in the control group, but this was clearly not the case in the current findings. Moreover, the offspring of the schizophrenic mothers tended to show notably lower rates of congenital malformations than did the offspring of their matched control subjects (table 1), and schizophrenia is the disorder for which the most evidence of early trauma and maldevelopment exists (1–6).

In contrast, the findings appear more to suggest that there is no relation between greater genetic risk and the occurrence of congenital malformations. If this interpretation is true, then the congenital malformations that are observed with greater frequency among persons who become schizophrenic are not the result of genetic influence associated with that disorder but, rather, are the result of other teratogenic influences of possible etiological relevance for psychosis.

# Wisconsin Card Sorting Test Performance in Schizophrenia: Remediation of a Stubborn Deficit

Michael Foster Green, Ph.D., Paul Satz, Ph.D.,
Steven Ganzell, Ph.D., and Jody F. Vaclav, B.A.

*Objective: Schizophrenic patients typically perform poorly on the Wisconsin Card Sorting Test, which is a putative index of prefrontal functioning. The authors attempted to remediate the deficits of schizophrenic patients on this measure by giving detailed instructions and monetary reinforcement. Method: Forty-six inpatients with chronic schizophrenia and 20 control subjects with other psychiatric illnesses were given the Wisconsin Card Sorting Test under four conditions that varied in monetary reinforcement and level of instructions. The schizophrenic patients were given the Brief Psychiatric Rating Scale (BPRS) and three information processing measures (the Continuous Performance Test, Span of Apprehension, and Pin Test). Results: Schizophrenic patients performed worse than psychiatric control subjects across most conditions. Monetary reinforcement had little effect on performance, but detailed instructions significantly improved the scores for both groups. When instructions were withdrawn and monetary reinforcement was maintained, both groups continued to show improved performance over baseline. Symptoms were not significantly associated with Wisconsin Card Sorting Test performance. One measure (the Pin Test) correlated significantly with performance on the Wisconsin Card Sorting Test. Conclusions: The results suggest the importance of combining motivational with instructional factors for training psychiatric patients in problem solving.*
(Am J Psychiatry 1992; 149:62–67)

The Wisconsin Card Sorting Test has attracted considerable attention from schizophrenia researchers recently. The amount of interest directed at this measure is somewhat surprising given that the Wisconsin Card Sorting Test is not new (it was developed in 1948 by Grant and Berg [1] and later modified by Milner [2]) and does not require high technology (simply a set of 128 cards). The Wisconsin Card Sorting Test requires subjects to match cards to one of four target cards on the basis of three rules (color, shape, or number of objects). The subjects are not told how to match the cards; they are simply told whether the match was correct or not. Based on this information, they are to figure out the correct sorting rule. If a subject makes 10 consecutive correct matches, the sorting rule changes without warning, and the subject needs to determine the new principle. To be successful on the Wisconsin Card Sorting Test, subjects need to 1) *attain* a concept (or rule), 2) *maintain* that concept for 10 consecutive trials, and 3) *switch* the concept when the rules for sorting change.

Much of the current interest in the Wisconsin Card Sorting Test rests on the hypothesis that the Wisconsin Card Sorting Test is a selective measure of frontal functioning (specifically, dorsolateral prefrontal functioning). Evidence that the Wisconsin Card Sorting Test assesses prefrontal functioning comes from two types of paradigms: lesion studies and activation studies. Several lesion studies with neurological patients (2, 3) have found that lesions to the prefrontal cortex have an especially adverse effect on test performance. Although this finding is widely reported, some studies have implicated the orbitomedial instead of the dorsolateral regions (4, 5), and other studies (6; unpublished 1990 paper of S.W. Anderson et al.) have failed to find a correspondence between frontal lesions and deficits on the sorting tests.

Received Jan. 25, 1991; revision received July 10, 1991; accepted July 26, 1991. From the UCLA Research Center, Camarillo State Hospital. Address reprint requests to Dr. Green, UCLA Research Center, Box 6022, Camarillo, CA 93011.

Funding for this project came from NIMH grant MH-43292. Data analysis, diagnostic training, and symptom assessment were supported by NIMH Clinical Research Center grant MH-30911. The software for the Continuous Performance Test and Span of Apprehension was developed by Drs. Keith Nuechterlein and Robert Asarnow with support from the John D. and Catherine T. MacArthur Foundation Network for Risk and Protective Factors in Major Mental Disorders.

The authors thank Donna Gaier, Maryam Aslani, Chad Nelson, Wade Schock, Julie Van Sickle, and Jennifer Smith for their help with the data collection. Sun Hwang, M.S., M.P.H., and Jim Mintz, Ph.D., conducted the statistical analyses. The study group was obtained through the cooperation of the staff and administration of Camarillo State Hospital.

In addition to lesion studies, activation studies have examined metabolic changes that accompany Wisconsin Card Sorting Test performance. Two elegant studies of regional cerebral blood flow (7, 8) reported that the metabolic activity in the dorsolateral prefrontal region increased in normal control subjects but not in schizophrenic patients when performing the Wisconsin Card Sorting Test. In addition, better performance for the schizophrenic patients correlated with greater metabolic activation in the dorsolateral prefrontal region. Although dysfunctions in other regions may impair Wisconsin Card Sorting Test performance (7), these findings were consistent with the hypothesis that a prefrontal defect impaired the performance of schizophrenic patients on the Wisconsin Card Sorting Test.

The question remains whether schizophrenic patients can improve their performance, presumably by activating the prefrontal region. In a study of schizophrenic children, Schneider and Asarnow (9) gave the Wisconsin Card Sorting Test without instructions for the first half (64 cards). The three sorting principles were then explained and demonstrated before administering the second half of the test. There was a tendency toward a reduction in the number of perseverative responses on the second half of the test, but the number of nonperseverative errors significantly increased after instruction, suggesting that additional task-relevant information can impair the performance of schizophrenic subjects.

In a study of adults with chronic schizophrenia, Goldberg et al. (10) reported that patients with extreme deficits on the Wisconsin Card Sorting Test improved their performance when they received trial-by-trial instructions. The instructions included information about the different categories and the shifting of the set. The improvement was not surprising because the experimenter essentially served as a surrogate frontal lobe for the subject. Interestingly, once the instructions were withdrawn the patients returned to their baseline deficit level of performance. This pattern suggested that schizophrenic subjects have a deficit on the Wisconsin Card Sorting Test that is not remediable.

These results are somewhat discouraging; they suggest that schizophrenic patients are not able to benefit from training in a problem-solving task. Because many of the current rehabilitation programs require patients to learn problem-solving techniques (11), the conclusions of Goldberg et al. challenge a central premise of psychiatric rehabilitation. However, before final conclusions are drawn, additional behavioral and/or motivational paradigms should be attempted.

Bellack et al. (12) successfully trained a small group of 12 schizophrenic patients on the Wisconsin Card Sorting Test. The subjects of Bellack et al. were less impaired and were given more sophisticated training than the subjects of Goldberg et al. For example, the subjects of Bellack et al. were given a longer training period and a shorter baseline period to minimize failure. Because the two studies (both of which await replication with larger groups of subjects) differed in both the severity of the patients' illness and the training procedure, it is not known which variable accounted for the successful training. In support of the idea that patient characteristics might influence performance, Braff et al. (13) found that outpatients with schizophrenia showed relatively mild deficits on the Wisconsin Card Sorting Test.

Bellack et al. did not find that monetary reinforcement without instructions improved performance on the Wisconsin Card Sorting Test. However, a recent report by Summerfelt et al. (14) found that monetary reinforcement alone was sufficient to improve performance on the Wisconsin Card Sorting Test. Hence, the role of monetary reinforcement remains unclear.

These studies raise several important questions: 1) By modifying the training procedure, can chronic, severely impaired patients be trained on the Wisconsin Card Sorting Test? 2) Do patients with psychiatric disorders other than schizophrenia show a different rate of improvement than patients with schizophrenia? and 3) What are the symptom and information processing correlates of Wisconsin Card Sorting Test performance? The present study describes an attempt to remediate the deficits of inpatients with chronic schizophrenia and psychiatric control subjects on the Wisconsin Card Sorting Test through monetary reinforcement and detailed instructions. In addition, we explored the symptom and information processing correlates of Wisconsin Card Sorting Test performance.

## METHOD

### *Subjects*

Forty-six patients with schizophrenia (33 men and 13 women) and 20 control subjects with other psychiatric illnesses (11 men and nine women) were tested on a computerized version of the Wisconsin Card Sorting Test. Partial Wisconsin Card Sorting Test data were collected from one patient with schizophrenia. All subjects gave informed consent after the procedures were fully explained. All were drawn from inpatient units of a state hospital.

All schizophrenic patients met *DSM-III-R* criteria for schizophrenia based on a version of the Present State Examination (15) supplemented with items from the Schedule for Affective Disorders and Schizophrenia (16). Interviewers were trained to a sensitivity of at least 0.85 and a specificity of at least 0.90 for key psychotic and affective symptoms in a university clinical research center for the study of schizophrenia. Potential subjects were excluded if they had a history of drug or alcohol dependence, an identifiable neurological disorder, or any signs of mental retardation (IQ less than 70) or if they were over 55 years of age. The study group was fairly chronic and received relatively large doses of neuroleptic medication (table 1).

The psychiatric control subjects were drawn from the same units as the schizophrenic patients, but they had chart diagnoses of substance abuse, substance dependence, or affective disorder without psychotic features.

**TABLE 1. Characteristics of Patients With Schizophrenia and Psychiatric Control Subjects Given the Wisconsin Card Sorting Test**

| Characteristic | Schizophrenic Subjects (N=46) | | Psychiatric Control Subjects (N=20) | |
|---|---|---|---|---|
| | Mean | SD | Mean | SD |
| Age (years) | 33.9 | 7.5 | 20.7 | 7.4 |
| Education (years) | 11.8 | 1.9 | 10.4 | 1.4 |
| Age at first hospitalization (years) | 20.3 | 4.4 | — | — |
| Time since first hospitalization (years) | 13.6 | 5.7 | — | — |
| Neuroleptic medication (mg/day, chlorpromazine equivalents) | 1097 | 815 | — | — |

Table 1 lists the available demographic data for both patient groups.

### *Symptom Ratings*

Symptom ratings for schizophrenic patients were based on an expanded version of the Brief Psychiatric Rating Scale (BPRS) (17). All raters were trained to a reliability of at least 0.80 (according to the median intraclass correlation coefficient) by the diagnostic unit of our clinical research center. Three indexes were derived from items on the expanded BPRS: 1) the psychotic index included unusual thought content, hallucinations, and conceptual disorganization, 2) the withdrawal/retardation index included blunted affect, motor retardation, and emotional withdrawal, and 3) the depression index included depressive mood, guilt, and suicidality.

### *Wisconsin Card Sorting Test*

A computerized Wisconsin Card Sorting Test (developed by Wang Neuropsychological Laboratory) was administered on an IBM PC-XT with a Taxan 720 color monitor. Subjects were shown a card and asked to match it by pointing to one of four target cards displayed on the monitor. An experimenter then pressed the button corresponding to the selected target card. The Wisconsin Card Sorting Test was administered in a single session to all subjects under four conditions (64 trials each) in the following order.

*Condition 1: baseline administration.* As recommended by Heaton (18), no information was provided to the subjects about the matching strategy.

*Condition 2: monetary reinforcement only.* Immediately after every correct response, two pennies were dropped into a bowl located next to the subject.

*Condition 3: monetary reinforcement plus detailed instructions.* Subjects continued to receive two cents for every correct response. In addition they received trial-by-trial instructions that were designed to approximate those used by Goldberg et al. (10). Subjects were told about the sorting principles ("There are three ways to match the cards: you can match the card by color, by the number of objects on the card, or by shape"). If the subject completed one set, he or she received additional instructions about the change of rules ("After you get 10 correct in a row, the rule changes; you are no longer matching to color, you must be matching to the number of objects or the shape"). After each correct answer, the subjects were told why it was right ("That's right, we are matching to color"), and after each wrong answer they were told the alternative sets ("That was wrong so we are not matching to the number of objects, we must be matching to color or shape").

*Condition 4: monetary reinforcement only.* This condition was identical to condition 2; the instructions were withdrawn and subjects continued to receive monetary reinforcement.

Dependent measures for the Wisconsin Card Sorting Test included the total number of correct responses (out of 64), the number of categories (sets) completed, and perseverative errors for each condition. Perseverative errors were scored according to the method of Heaton (18).

### *Information Processing Measures*

A subgroup of 27 of the schizophrenic patients were also included in a separate protocol and received three information processing tests and the BPRS.

*Pin Test.* The Pin Test (19) is a motor sequencing test that measures neuromotor speed and dexterity. Subjects sat in front of a small metal template with a series of holes drilled through it in a sinusoidal pattern. They were instructed to use a straight pin to quickly punch holes through the template into a piece of resistance cardboard and a recording sheet of paper placed between the template and cardboard. Subjects performed this twice with each hand for 30 seconds. The dependent measure was the average number of pin holes for each hand.

The other two information processing measures were presented on an IBM-PC computer with a Taxan 720 color monitor. Viewing distance was 1 m, and subjects responded by pressing a response button.

*Degraded-Stimulus Continuous Performance Test.* The Degraded-Stimulus Continuous Performance Test is a measure of visual vigilance (20). Version 1 of the UCLA Continuous Performance Test computer program was used (unpublished manual and program by K.H. Nuechterlein and R.F. Asarnow). Subjects were instructed to press a response button whenever they saw the target number, zero. The numbers were degraded to a standardized degree by randomized pixel reversal. Subjects were shown a series of 160 practice trials followed by 480 experimental trials. For all trials, the stimuli were presented for 60 msec at 1-sec intervals. The target zero appeared in a quasi-random sequence 20 out of every 80 trials.

The dependent measures for the Degraded-Stimulus Continuous Performance Test included vigilance level (a measure of signal-to-noise discrimination measured by the nonparametric statistic A') and vigilance decrement (the change in vigilance level calculated by subtracting A' of the last third of the test from the first third).

*Span of Apprehension.* The Span of Apprehension is an index of early iconic memory and readout stages of visual processing (21). Version 1 of the UCLA Span of Apprehension computer program was employed (unpublished 1987 manual and program by R.F. Asarnow and K.H. Nuechterlein). Subjects were told that letters would be flashed on the screen and that either the letter T or the letter F would be in each array. Either two or 11 nontarget letters were placed randomly in other positions of the array. Each array size was presented in blocks of 16 trials, and an equal number of Ts and Fs appeared within each block. Four blocks of each size array were administered. Subjects received 20 practice trials to become familiar with the procedure.

Due to a ceiling effect for the smaller array, only the results for the larger array were considered in the current study. The dependent measures were the number of correct responses and the mean reaction time for correct responses.

### Statistical Analyses

To examine the effects of the conditions, two-factor (group by condition) analyses of variance (ANOVAs) were conducted for each of the three measures from the Wisconsin Card Sorting Test (number correct, perseverative errors, and number of categories completed). The Greenhouse Geisser probabilities were used for all within-subjects analyses. Follow-up comparisons were made when appropriate. In the presence of interactions, main effects are cited only if they are ordinal (i.e., consistent across levels of the other factor) (22, p. 204).

For examining the relationships between information processing, symptoms, and measures from the Wisconsin Card Sorting Test, Pearson product-moment correlations were used.

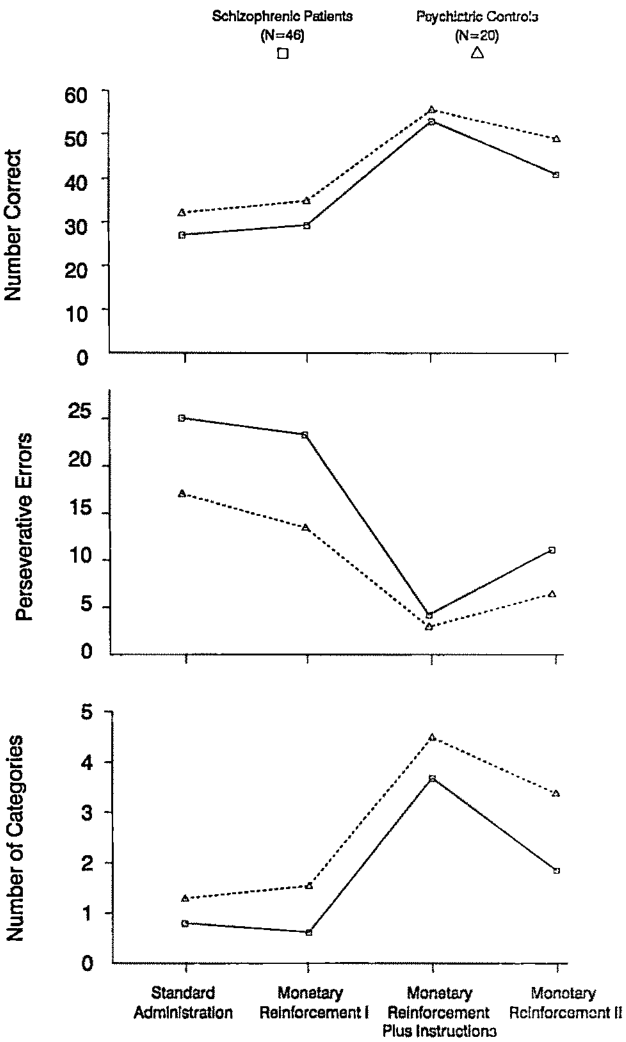
## RESULTS

### Training on the Wisconsin Card Sorting Test

For baseline, condition 1, the mean scores for the schizophrenic patients were $27.2\pm10.7$ for number correct, $25.1\pm13.9$ for perseverative errors, and $0.80\pm1.1$ for categories completed. The psychiatric control subjects showed a trend for better performance than the schizophrenic patients for number correct ($32.1\pm11.4$) ($t=1.70$, df=64, $p=0.09$) and categories completed ($1.3\pm0.9$) ($t=1.73$, df=64, $p=0.09$), and their scores were significantly better for perseverative errors ($17.1\pm12.7$) ($t=2.22$, df=64, $p<0.05$). These data are illustrated in figure 1.

*Number correct.* The effect for condition ($F=123.5$, df=3, 189, $p<0.0001$) and the effect for group ($F=7.51$, df=1, 63, $p<0.01$) were significant for the total number correct. The interaction was not significant ($F=1.20$). In the absence of an interaction, the two groups were combined for comparisons with baseline. The scores from conditions 3 and 4 were significantly higher ($p<0.0003$ after Bonferroni correction) than baseline, but the scores from condition 2 did not differ from baseline.

**FIGURE 1. Performance of Schizophrenic Patients and Psychiatric Control Subjects on the Wisconsin Card Sorting Test Under Four Conditions**



*Perseverative errors.* The effect for condition ($F=57.1$, df=3, 189, $p<0.0001$), the effect for group ($F=8.88$, df=1, 63, $p<0.01$), and the group by condition interaction ($F=3.11$, df=3, 189, $p<0.05$) all reached significance for perseverative errors. Comparisons with baseline were conducted separately for each group. The results followed the same pattern for both groups: scores from conditions 3 and 4 were significantly better than those from baseline ($p<0.006$ with Bonferroni adjustment), but the scores from condition 2 were not significantly different from baseline. The significant interaction can be attributed to a trend ($F=3.53$, df=1, 64, $p=0.065$) for the groups to differ less at condition 3 than at condition 1 (likely due to a floor effect on condition 3).

*Categories.* The ANOVA for the number of completed categories showed significant effects for condition ($F=118.2$, df=3, 189, $p<0.0001$), group ($F=15.67$, df=1, 63, $p<0.0005$), and group by condition interac-

**TABLE 2. Correlations Between Number Correct on the Wisconsin Card Sorting Test and Information Processing Measures for 27 Schizophrenic Patients**

| | Correlation (r)[a] | | |
|---|---|---|---|
| Measure | Standard Administration (Condition 1) | Monetary Reinforcement II (Condition 4) | Partial Correlation[b] |
| Degraded-Stimulus Continuous Performance Test | | | |
| Vigilance level | –0.22 | –0.09 | 0.05 |
| Vigilance decrement | –0.17 | –0.21 | –0.14 |
| Span of Apprehension | | | |
| Number correct | 0.28 | 0.26 | 0.12 |
| Latency | –0.15 | –0.11 | –0.03 |
| Pin Test | | | |
| Right hand | 0.64[c] | 0.51[d] | 0.24 |
| Left hand | 0.47[e] | 0.41[e] | 0.21 |

[a] Multiple $R^2$ values were 0.50 for condition 1 and 0.38 for condition 4.

[b] The partial correlation is between the information processing measures and the number correct in condition 4 after partialling out the number correct from condition 1.

[c] $p<0.001$.

[d] $p<0.01$.

[e] $p<0.05$.

tion ($F=2.99$, $df=3, 189$, $p<0.05$). Comparisons were made separately for each group. Similar to the results for perseverative errors, both groups differed from baseline in conditions 3 and 4 ($p<0.0003$ after Bonferroni correction) but not in condition 2. The significant interaction can be attributed to a significantly larger difference between groups at condition 4 than at condition 1 ($F=5.8$, $df=1, 64$, $p<0.02$), suggesting that the psychiatric control subjects might have showed more improvement during the final condition.

### *Correlates of Test Performance*

Pearson product-moment correlation coefficients were obtained between each of the six information processing measures and the number correct (table 2). The three measures from the Wisconsin Card Sorting Test were highly intercorrelated, and the number correct was chosen because it shared the most variance with the other two measures. We looked at the number correct for condition 1 and condition 4 and at the partial correlation with condition 4 controlling for condition 1, which gives an indication of the amount of change during the session. The measures from the Degraded-Stimulus Continuous Performance Test or the Span of Apprehension did not show significant correlations with the Wisconsin Card Sorting Test variables for condition 1 or for improvement across conditions. However, both the left- and right-hand scores from the Pin Test showed moderate correlations with the number correct. This relationship seemed to generalize to other Wisconsin Card Sorting Test variables because the Pin Test also showed moderate correlations with categories ($r=0.61$ for right hand, $r=0.48$ for left hand) and perseverative errors ($r=-0.47$ for right hand, $r=-0.34$ for left hand) for condition 1.

The means and standard deviations of the BPRS indexes for these 27 schizophrenic patients were 10.1±4.1 for the psychotic index, 5.8±2.6 for depression, and 8.0±4.0 for withdrawal/retardation. Correlation coefficients were obtained between each of the three BPRS indexes and the Wisconsin Card Sorting Test measures. These correlations ranged from –0.03 to 0.17, and none reached significance.

## DISCUSSION

The present results suggest that the performance deficits of schizophrenic patients on the Wisconsin Card Sorting Test can be remediated by a combination of reinforcement and detailed instructions. Although the psychiatric control subjects performed somewhat better than the schizophrenic patients, the effects of the interventions were comparable. In the light of previous studies by Goldberg et al. (10) and Bellack et al. (12), our results suggest that even patients with chronic schizophrenia can show short-term benefits from training. Although direct comparisons are difficult, the current study group is probably much closer to the study group of chronically ill patients of Goldberg et al. than the study group of acutely ill patients of Bellack et al. The Bellack et al. subjects were comparable to our subjects in their scores on the psychotic items of the BPRS (average of 3.3 versus 3.4), but their subjects had been hospitalized for an average of 20 days before testing while ours were hospitalized for an average of 9.7 months before testing.

The use of reinforcement alone did not significantly improve Wisconsin Card Sorting Test performance. Perhaps the amount of reinforcement was not sufficient (2 cents per response). Bellack et al. (12) reinforced 5 cents per response but did not notice a beneficial effect. However, Summerfelt et al. (14) reported improved performance when they gave schizophrenic patients a stake ($7.50) and then paid them 10 cents for each correct response and penalized them 5 cents for each wrong response. These results indicate that some subjects might benefit from monetary incentives that are larger than were used in the present study.

The introduction of detailed instructions improved performance, and this improvement was largely maintained shortly after the withdrawal of instructions. Although it was not specifically tested, the continuation of monetary reinforcement might have accounted for the maintenance of improved performance. It is entirely possible that the present study group (like that of Goldberg et al.) would have returned to baseline levels of performance without the reinforcement, especially considering that our patients initially performed worse than did those of Goldberg et al. (e.g., our patients completed 1.5 categories and their patients completed 3 categories in the first 128 trials). It would be valuable to follow up these findings with a between-group design that could directly compare the impact of reinforcement with that of instructions.

When applied to rehabilitation efforts, our results suggest the importance of combining motivational with specific instructional factors for training in problem solving. In terms of neuroanatomy, the results might indicate that effective remediation requires involvement of both prefrontal and limbic regions.

A fairly striking correlation was observed between the Wisconsin Card Sorting Test variables and Pin Test results in the first and last conditions. This association deserves closer scrutiny. Perhaps neuromotor sequencing might yield a more basic measure of activation that operates at a precognitive stage and underlies higher-level processing.

In contrast to a recent study by Braff et al. (13), negative symptoms were not found to be associated with Wisconsin Card Sorting Test performance. Compared with the study group of Braff et al., our schizophrenic patients had substantially more impairment on the Wisconsin Card Sorting Test, had more chronic illness, and may have had more deficit symptoms. Hence, the range of our analyses might have been comparatively restricted.

For future research in this area, investigators are encouraged to look both "inward" (to identify the nature of Wisconsin Card Sorting Test deficits) and "outward" (to see if these deficits correspond to adaptive functioning). The Wisconsin Card Sorting Test requires subjects to attain a concept, maintain the concept, and switch the concept. Much interest has been devoted to problems in switching the concept: perseverative errors are often chosen as the dependent measure. Although our subjects showed considerable perseverative errors, 54% could not attain a single category in the first 64 trials. Hence, our subjects also had problems in attaining and/or maintaining concepts.

The generalizability of Wisconsin Card Sorting Test performance can be addressed empirically. For example, successful learning on the Wisconsin Card Sorting Test with instruction and reinforcement might be associated with success in skills training procedures. We had previously hoped to identify groups of learners and nonlearners based on their improvement on the Wisconsin Card Sorting Test (23). However, the improvement scores showed a negatively skewed distribution without a point of rarity and did not support the notion of distinct subgroups. Nonetheless, initial screening of problem-solving capacity might yield an empirical basis for selecting patients who are most likely to benefit from social and behavioral rehabilitation programs.

# Clozapine-Induced Weight Gain: Prevalence and Clinical Relevance

Robert Leadbetter, M.D., Michael Shutty, Ph.D., Diane Pavalonis, R.N., M.S.N.,
Victor Vieweg, M.D., Patricia Higgins, M.S.W., and Marylou Downs, R.N., Ph.D.

*Objective: The aim of this study was to determine the prevalence and clinical relevance of weight gain during clozapine treatment. Previous reports indicated clinically significant weight gain in 13% to 85% of patients and an average gain of 9.0 to 24.7 lb. Method: Twenty-one state hospital patients with treatment-resistant schizophrenia or schizoaffective disorder were weighed weekly for 12 weeks before clozapine treatment and during the first 16 weeks of treatment. Psychiatric symptoms were rated with a modified version of the Brief Psychiatric Rating Scale (BPRS). Results: The mean weight gain for the entire group was 13.9 lb, or 8.9% of body weight. During the 16 weeks of clozapine treatment, 38% of the patients experienced marked weight gains and 29% had moderate weight gains. The improvements in BPRS total score and composite negative symptom score were significantly greater for the eight patients with marked weight gains than for the other 13 patients. Conclusions: Clozapine's propensity to induce weight gain may relate to the drug's efficacy and/or its unique neuropharmacologic effects. Increased attention to this phenomenon is important because of the morbidity associated with obesity.*

(Am J Psychiatry 1992; 149:68–72)

Many patients with schizophrenia suffer from obesity (1–3), which is associated with excessive rates of morbidity and mortality (4). Institutionalization, lack of exercise, poor diet, and misperception of satiety have been linked to the high prevalence of obesity in schizophrenia (2, 3, 5, 6). Studies have shown that weight changes relate to the severity of psychosis (3) and that weight gain is associated with clinical improvement (3, 7–9).

Chlorpromazine treatment is frequently associated with weight gain (3, 4, 8–12). Other standard antipsychotic drugs associated with weight gain include perphenazine and clopenthixol (4), fluphenazine (12–16), and thiothixene, haloperidol, and thioridazine (12). In contrast, molindone (10, 17) and loxapine (12) appear to cause weight loss. Amdisen (4) found that patients treated with antipsychotic agents reached weights associated with mortality rates 35% to 100% higher than normal. Singh et al. (7) showed that perphenazine increases appetite and caloric intake and perhaps increases metabolic efficiency and alters the body weight set point.

Clozapine is an atypical antipsychotic considered to have superior efficacy for patients with treatment-resistant psychosis (18). The drug's manufacturer noted a 1% prevalence of weight gain among 13,000 patients (19). However, as early as 1975 Norris and Israelstam (20) reported dramatic clozapine-induced weight gain in a group of 13 hospitalized adolescents with behavioral problems or acute schizophrenia. Nine of these patients "experienced an enormous increase in appetite," and four patients gained 22–44 lb during the first 2 months of treatment. Since then, various studies (21–27) have associated weight gain with clozapine treatment in 13% to 85% of patients, and the average weight gain was 9.0 to 24.7 lb. This wide range of reported weight gains stems in part from methodological differences among studies. For example, whether weight fluctuations were assessed during medication withdrawal is unclear in most reports. Also, other clinical or neurobiological factors correlating with weight changes were not accounted for in these patients.

During the preclinical trials of clozapine, we noted that many patients gained weight early in treatment

(28). Because of the wide variance in the amounts of weight gained in previous studies and the discrepancy between these findings and the drug company's data, we examined the prevalence and magnitude of clozapine-induced weight gain, the clinical correlates of this problem, and the neurobiological factors that might explain this phenomenon.

**TABLE 1. Individual Weight Changes in Patients Receiving Clozapine**

| Patient | Sex | Weight (lb)<br>Before Clozapine | Weight (lb)<br>Week 16 | Change<br>Pounds | Change<br>% |

## METHOD

### *Subjects and Procedure*

We studied 21 patients at a 600-bed state psychiatric facility. The subjects were 13 men and eight women, and their mean age was 32.6 years (range=19–47). The inclusionary criteria were a diagnosis of schizophrenia or schizoaffective disorder (*DSM-III-R*) and one of the following: 1) lack of response to adequate trials of several standard antipsychotic drugs, 2) intolerable side effects of those drugs, or 3) tardive dyskinesia. The exclusionary criteria were 1) a history of drug-induced agranulocytosis, 2) bone marrow abnormalities, or 3) a primary seizure disorder.

Treatment with carbamazepine and depot neuroleptic agents was stopped 2 weeks before the beginning of clozapine treatment. Standard antipsychotic and anticholinergic drugs were tapered over 1–4 weeks; the drug-free period was 24 to 48 hours. We increased the clozapine dose from 25 to 125 mg/week as tolerated and titrated the dose until a therapeutic response was achieved. We weighed the patients weekly with standard (counter-weight) hospital scales during the 12 weeks before and 16 weeks after the beginning of clozapine treatment, and ideal weight was based on established formulae (29).

We chose a modified version of the Brief Psychiatric Rating Scale (BPRS) to rate symptoms (30). A trained rater used a semistructured interview format to interview the patient and then consulted with other staff members and reviewed the patient's record before deriving a BPRS score. All ratings related to the patient's functioning during the prior week. The intraclass correlation coefficient for BPRS ratings of 13 videotaped interviews was 0.77 for eight trained multidisciplinary staff members.

### *Statistical Analyses*

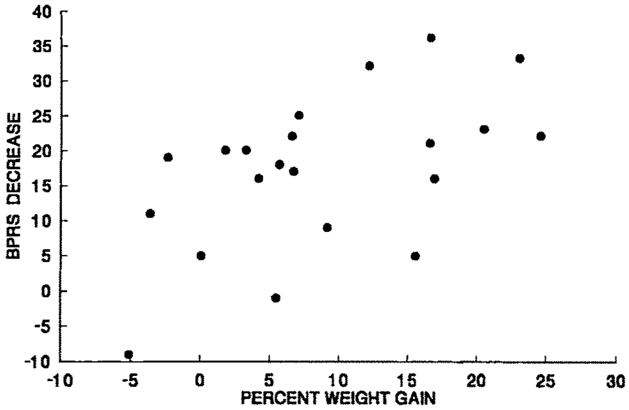
We conducted our statistical analyses in three phases. First, we compared the patients' weekly weights during the 12-week baseline period to the weights in the first 12 weeks of clozapine treatment, both as a group and individually, to assess whether a net weight gain was evident after conversion from standard neuroleptics to clozapine. We evaluated pre-post changes in weight gain using two-tailed, paired t tests. All remaining analyses focused on the weight changes from the start of clozapine treatment to the 16th week of treatment. We divided the patients into two groups on the basis of amount of weight gained and determined group differences in age, gender, pretreatment deviation from ideal body weight, and amount of weight change during tapering of standard antipsychotics. Third, we explored the clinical aspects of weight gain by comparing group differences in concurrent treatment with lithium and in psychiatric symptom ratings, using BPRS total scores and composite positive and negative symptom scores (18). Where appropriate, we used two-tailed, unpaired t tests and chi-square analyses and employed Bonferroni corrections to adjust the type I error rate in each of the three sets of analyses to guide our interpretation of statistical significance.

## RESULTS

As a group, the patients weighed significantly more during the first 12 weeks of clozapine treatment than during the preceding 12 weeks ($t=2.86$, $df=20$, $p<0.01$). When the patients were examined individually, it was found that 13 (62%) experienced significant increases in weight (Bonferroni correction, $p<0.05$). Seven (33%) of the patients lost weight during the tapering of standard antipsychotics, but the absolute weight change across patients was significantly less during the baseline period (mean= –0.44 lb) than during the first 12 weeks of clozapine treatment (mean=+13.8 lb) ($t=4.05$, $df=20$, $p<0.001$).

Table 1 presents each patient's weight at the onset of clozapine treatment and the weight at the 16th week of treatment. Eight patients experienced marked weight gains (greater than 10% increase), six had moderate

**FIGURE 1. Correlation Between Decrease in Total BPRS Score and Percentage of Weight Gained During 16 Weeks of Clozapine Treatment in 21 Patients[a]**



[a] r=0.54, df=19, p=0.01.

weight gains (5%–10% increase), four had mild to minimal weight gains (less than 5% increase), and three patients lost weight. Across all patients, the mean weight gain was 13.9 lb, or 8.9% of baseline body weight. Weight gain was particularly evident during the second half of the 16-week clozapine trial, as the doses reached therapeutic levels.

On the basis of the distribution of patients, we made a conservative decision to compare the eight patients who experienced marked weight gains (mean=28.8 lb) with the other 13 patients (mean gain=5.4 lb). There were no group differences in age, gender, deviation from ideal weight at the start of the drug trial, or amount of weight change during tapering of standard antipsychotics. Although the difference was not statistically significant, the mean pretreatment dose of standard neuroleptics, in chlorpromazine equivalents, was higher in the patients with marked weight gains (41.4 mg/kg, range=1.3–111.5) than in those who gained less weight (24.4 mg/kg, range=4.7–49.7). At 16 weeks there was no difference between groups in clozapine dose. The group of patients concurrently treated with lithium tended not to gain weight (Fisher's exact test, p<0.18); only two (20%) of these 10 patients experienced marked weight gains while taking lithium, whereas six (55%) of the 11 patients not treated with lithium had marked weight gains.

As indicated in figure 1, decrease in total BPRS score showed a significant positive correlation with percentage of weight gained. The patients who gained at least 10% of their body weight showed a significantly greater decrease in total BPRS score (mean=23.5) than the patients with less weight change (mean=13.3) (t=2.29, df=20, p<0.03). When we analyzed decreases in composite positive and negative symptom subscale scores separately, we found that the two groups' negative symptom scores were significantly different (t=2.61, df=20, p<0.02). Those with marked weight gains showed an average decrease of 6.0 on the negative symptom subscale, and those with less weight change showed an average decrease of 2.5.

In a second set of analyses we recalculated BPRS scores to reflect presence or absence of symptoms (no score=0, any score=1). These analyses corroborated the previous finding that a significant relationship existed between improvement and weight gain. Not only was there a significant difference between groups in the number of negative symptoms (t=2.58, df=20, p<0.02), but the number of positive symptoms also differed between groups (t=2.23, df=20, p<0.04). The subjects with marked weight gains showed an average reduction of 1.12 positive and 1.62 negative symptoms, compared with average reductions of 0.23 positive and 0.46 negative symptoms for those with less weight change.

## DISCUSSION

We found that 62% of patients weighed significantly more during the first 12 weeks of clozapine treatment than during the 12-week baseline. Although one-third of our patients lost weight during the tapering of standard antipsychotics before clozapine treatment, the weight loss during tapering was of significantly less magnitude than the weight gain during clozapine treatment. Also, there was no baseline weight difference between those who did and did not gain weight during clozapine treatment. To focus on true weight gain due to clozapine treatment we compared the absolute weight at the start of clozapine treatment to the weight at week 16 of treatment.

Fourteen (67%) of the 21 patients gained more than 5% of their baseline body weights. Previous reports addressing clozapine-induced weight gain indicated that 13% to 85% of patients experience this side effect (20–25, 27). Weight gains associated with standard antipsychotic drug treatments range from 14.5% to 80.0% (4, 7, 13, 14). Among our patients, clozapine was associated with a mean weight gain of 13.9 lb during the 16 weeks of treatment; previous studies showed an average gain of 9.0 to 24.7 lb over variable lengths of clozapine treatment (21, 23, 26, 27). In contrast, weight gains associated with standard antipsychotic drugs range between 3.4 and 9.0 lb over 12 weeks (8, 12).

A critical examination of this study requires attention to a number of clinical variables. There was no change in the patients' diets or access to food during this study, although we did start nutritional education once we noted weight gain. Several patients did complain of an inability to suppress appetite after a full meal, suggesting a change in satiety perception. Clozapine is frequently sedating, but we found that psychomotor retardation improved more in the patients with marked weight gains than in those who gained less weight. The mean chlorpromazine-equivalent dose was significantly lower during clozapine treatment than during the preceding treatment with standard antipsychotic agents. If there is a correlation between dose and weight gain, as one author has suggested (4), we should have noted weight loss during this study.

We noted a significant correlation between weight gain and improvement in total BPRS score. There also was greater improvement in the composite negative symptom score in the patients with marked weight gains. Reports do indicate that during treatment with standard antipsychotic drugs weight gain correlates with a decrease in psychosis (3, 7–9), although some authors disagree (4, 5). Alternatively, weight gain may be due to the psychotropic's effect on CNS mechanisms (31).

Characteristic neurotransmitter and neuroendocrine effects of antipsychotic agents could explain differences in their propensity to induce changes in weight and appetite regulation (32). For example, clozapine's ability to alter plasma cortisol concentration (33, 34), its adrenolytic effects (which have been attributed to clozapine-induced hyperphagia in rats [35]), and its unique $D_1$ and $D_2$ neurotransmitter effects (36–38) could be important factors in its induction of weight gain. Clozapine's potent serotonin antagonism (33) may be important, because serotonin agonists suppress appetite (39, 40), and other psychotropic drugs that either antagonize or down-regulate serotonin receptors, such as chlorpromazine (41) and fluphenazine (15), are more likely to stimulate carbohydrate craving and weight gain (31). We observed that lithium, which influences serotonin transmission (42), tended to protect patients from weight gain.

We have continued to follow clozapine-induced weight gain in this group of patients and have found that the rate of weight gain was greatest during the first 16 weeks of treatment and that the rate of weight gain decreased with time. At this point, one cannot absolutely rule out a variety of biological variables in explaining the etiology of weight gain. Nonetheless, we have shown an association between clozapine-induced weight gain and clinical improvement in patients who were previously treatment resistant. Perhaps clozapine would be useful in the treatment of end-stage anorexia nervosa, given that this illness is often treatment resistant and quasipsychotic. In the chronically mentally ill, however, increased attention to drug-induced weight gain is important because of the greater susceptibility to weight gain associated with clozapine and concomitant excessive morbidity and mortality.

# Seasonal Patterns of Bulimia Nervosa

Arthur Blouin, Ph.D., Jane Blouin, Ph.D., Peter Aubin, B.A., Jacqui Carter, B.A., Cathy Goldstein, M.A., Helene Boyer, B.A., and Edgardo Perez, M.D.

*Objective: The aim of this research was to determine whether a seasonal pattern to symptoms of bulimia nervosa could be identified. Method: In study 1, seasonal patterns of binge-purge frequency and mood were compared between 31 patients with bulimia nervosa and 31 age-matched normal comparison subjects, using a modified (to include binge and purge items) version of the Seasonal Pattern Assessment Questionnaire. Study 2 involved a cross-sectional examination of binge and purge frequency and of depressive symptoms in 197 patients with bulimia nervosa assessed at various months of the year over a 4-year period. Results: In both the retrospective and cross-sectional studies, binge behavior was found to be highly associated with photoperiod. According to the modified Seasonal Pattern Assessment Questionnaire, purging behavior and mood also varied seasonally among patients with bulimia nervosa. However, purging behavior and severity of depression did not appear to be related to photoperiod in the cross-sectional study. The rate of seasonal affective disorder (syndromal and subsyndromal) defined by the Seasonal Pattern Assessment Questionnaire was higher among the bulimic group than the comparison subjects, but not as high as has been reported for depression in bulimia nervosa. Conclusions: The results strongly support the interpretation that symptoms of bulimia nervosa primarily associated with food intake patterns are influenced by seasonal variation, and this effect may be mediated by light availability.*

(Am J Psychiatry 1992; 149:73–81)

To date, seasonal patterns in bulimia nervosa have not been well documented. Evidence to suggest that bulimia nervosa is sensitive to seasonal patterns is indirect and arises from a single study that examined symptoms of seasonal affective disorder among patients with bulimia nervosa. Fonari et al. (1) found that patients with bulimia nervosa reported feeling worse and eating more in the winter than at other times of the year. Although this seasonal effect was greater for bulimic patients than for normal control subjects, it was not equivalent to the effects reported by patients with seasonal affective disorder (1). Rosenthal et al. (2) have suggested that binge eating in bulimia nervosa may follow a seasonal pattern, since patients with bulimia nervosa and patients with seasonal affective disorder share common symptoms, including carbohydrate craving and binge eating (3, 4).

The cardinal symptom of bulimia nervosa is defined in *DSM-III-R* as recurrent episodes of binge eating. Depressed mood is listed as a common associated feature. The cardinal feature of seasonal affective disorder, according to *DSM-III-R*, is an affective disturbance with recurrent onset in a particular 60-day period of the year. Two of the most common associated features of seasonal affective disorder are increased appetite and carbohydrate craving (2–4). This is in contrast to nonseasonal depression, which is typically associated with loss of appetite and is less frequently associated with carbohydrate craving than is seasonal affective disorder (5). In addition to sharing similar affective and appetitive symptoms, bulimia nervosa and seasonal affective disorder share the feature of gender specificity. Bulimia occurs predominantly in females (over 90%) (6), as does seasonal affective disorder (over 80%) (2–4). It has been demonstrated that the symptoms of both bulimia nervosa and seasonal affective disorder respond to increased central serotonergic activation. Both fenfluramine and fluoxetine have been shown to be effective in treating bulimia nervosa (7, 8), and fenfluramine has also been reported to be effective in seasonal affective disorder (9, 10).

The present study examined seasonal patterns of

binge eating, purging, and mood in bulimia nervosa. Previous studies of seasonal effects on mood have relied on the Seasonal Pattern Assessment Questionnaire (3), which has been demonstrated to be highly sensitive to seasonal effects (11). However, the questionnaire relies on retrospective self-report and may be biased by subject expectation. To address this weakness, the present study incorporated two separate methodological approaches. The first is in keeping with previous studies, comparing the results of the Seasonal Pattern Assessment Questionnaire among a group of patients with bulimia nervosa and a normal comparison group. The normal comparison group is included in order to determine whether the questionnaire reports of seasonal variation in mood exceed those of a group without eating disorders and of comparable age and sex. The second study is a cross-sectional examination of bulimic and depressive symptoms reported by patients with bulimia nervosa as part of their first clinical intake assessment during different months of the year.

## STUDY 1

### *Method*

*Subjects.* Thirty-one volunteer subjects who met *DSM-III-R* criteria for bulimia nervosa were selected from a group of 58 patients consecutively referred to the eating disorders clinic of a large (900-bed) urban general hospital. Excluded were referred patients who did not meet *DSM-III-R* criteria for bulimia nervosa. All subjects were women and of normal weight. Three had a lifetime history of anorexia nervosa. They were not receiving treatment for their eating disorder at the time of the study. The diagnoses of bulimia nervosa and anorexia nervosa were based on 1) the subjects' responses to the bulimia and anorexia nervosa sections of the National Institute of Mental Health Diagnostic Interview Schedule (DIS) (12) and 2) positive diagnosis based on psychiatric interview. The diagnoses were further confirmed by subjects' responses to the Diagnostic Schedule for Eating Disorders (13) and to the Eating Disorders Inventory (14). The diagnosis of depression was based on subjects' responses to the depression section of the DIS.

Thirty-one normal comparison subjects, comparable in age to the bulimic subjects, were selected from a volunteer group of 61 female university students and 36 female hospital employees. The only criteria used in selecting the comparison group were that 1) they volunteered, 2) they had no history of an eating disorder, according to their responses to the bulimia nervosa and anorexia nervosa sections of the DIS (12), and 3) as a group, their age was comparable in distribution and range to that of the bulimic subjects. All volunteer subjects signed informed consent forms, and the entire protocol was approved by the Research Ethics Committees of the Ottawa Civic Hospital and Carleton University.

*Procedure.* Patients attending the eating disorders clinic routinely undergo a comprehensive intake that includes the DIS, a psychiatric interview, and complete psychological assessment. Each subject in the present study (patients and comparison subjects) completed a modified version of the Seasonal Pattern Assessment Questionnaire (3). The questionnaire has been demonstrated to have acceptable test-retest reliability and discriminant validity (11). It is divided into seven sections: 1) demographics, 2) degree of change in seasonal affective disorder symptoms, 3) months most affected, 4) climatic changes, 5) changes in weight and food preference, 6) sleep, and 7) extent to which seasonal affective disorder changes are problematic. Section 2 presents six 5-point scales (0="no change," 4="extremely marked change") measuring length of sleep, social activity, mood, weight, appetite, and energy level. The first criterion for seasonal affective disorder is that the sum of the subject's scores for each of these items is greater than 10. The second criterion is a report, in the seventh section of the questionnaire, of "moderate" to "disabling" problems with seasonal changes. Subsyndromal seasonal affective disorder was identified by a seasonality score of 10 with mild or less seasonal problems, or a seasonality score of 8 or 9 with at least mild problems with seasonal changes.

The third section of the Seasonal Pattern Assessment Questionnaire asks subjects to indicate the months in which they are most likely to experience certain behaviors, by making a yes/no response for each month, for each behavioral item. The items include "feel best," "feel worst," "gain most weight," "lose most weight," "socialize most," "socialize least," "sleep most," "sleep least," "eat most" and "eat least." For the purpose of this study, the questionnaire form was modified so that three-letter monthly abbreviations were displayed immediately above the recording location for each month, for every item, rather than a single letter at the bottom of the column for all items, as on the original form. The modified questionnaire used the same format to assess the months in which the subject was most likely to binge and to purge.

Meteorological data included monthly means for hours of bright sunshine, global solar radiation (measured in megajoules per square meter of energy striking a horizontal surface), temperature, and precipitation in Ottawa, averaged separately for each month for the years 1951 to 1980. These data were obtained from the 1989 Annual Meteorological Summary published by Environment Canada for Ottawa (15). Data on photoperiod were obtained from the Herzberg Institute of Astrophysics of the National Research Council of Canada, using formulae published elsewhere (16). Ottawa is situated at 45°19'N latitude, 75°40'W longitude. The city has a marked continental climate with relatively large temperature variations throughout the year. Average temperature extremes range from –15 °C during January to 26 °C in July. Over the year, there is an average of 2,008 hours of bright sunshine. July normally has the greatest number of sunny hours (274 hours) and December the least (79 hours) (15).

[a] Hollingshead and Redlich (17).

*Statistical analysis.* The analysis of variance (ANOVA) employed one between-subjects factor (group: bulimic versus comparison group) and one within-subjects factor (month: January through December). Dependent measures included the self-reports of months when the subjects were most likely to binge, purge, and experience the 10 other behaviors and feelings itemized in section 3 of the modified Seasonal Pattern Assessment Questionnaire. Significant ANOVA results were followed with univariate tests of differences between the two groups for each month.

A multivariate ANOVA was used to test the significance of differences between the bulimia nervosa and normal comparison groups in response to items in section 2 of the Seasonal Pattern Assessment Questionnaire that assess the degree to which the respondent is affected by seasonal change in six areas. A significant multivariate effect was to be followed with six univariate ANOVAs.

Photoperiod was converted to "dark hours" (24 hours minus the average photoperiod for each month) in order to enhance the graphical display of the association between bulimic symptoms and photoperiod. The dark hours included twilight hours at dusk and dawn. Pearson correlations were calculated between 1) the meteorological variables (dark hours, hours of bright sunshine, global solar radiation, temperature, and precipitation) averaged for each month and 2) the proportion of patients who reported on the Seasonal Pattern Assessment Questionnaire a given month as the month in which they were most likely to binge, purge, or feel worst. These correlations were based on group results, yielding a total of 12 (one for each month) for each correlation. Correlations were calculated separately for the bulimia nervosa group and the normal comparison group results.

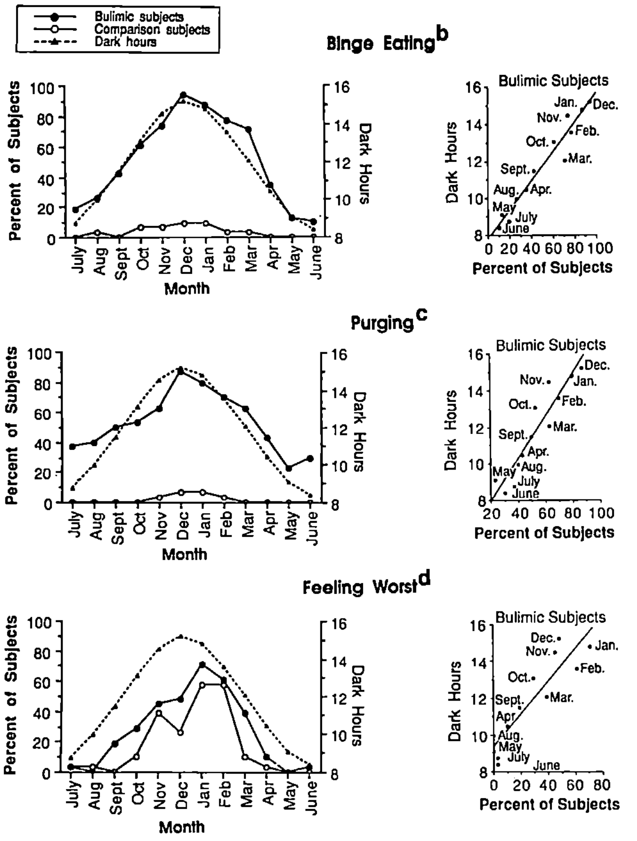
### *Results*

*Group characteristics.* Characteristics of the bulimic and comparison groups appear in table 1. Both groups averaged 24 years of age and were of equivalent socioeconomic status. Fewer of the bulimic patients were married, and the bulimic patients tended to report a higher body weight, but neither of these differences attained statistical significance. The bulimic group binged an average of 8.7 times per week and purged an average of 11.2 times per week.

Among the bulimic group, 11 (35.5%) of the 31 patients met the criteria of the Seasonal Pattern Assessment Questionnaire for either seasonal affective disorder (eight patients) or subsyndromal seasonal affective disorder (three patients). This frequency was significantly higher ($\chi^2$=6.23, df=1, p<0.02) than the two (6.5%) (one syndromal, one subsyndromal) reported in the comparison group. Among the bulimic patients, 15 (48.4%) reported symptoms of a lifetime history of major depressive disorder. There was no association between frequency of seasonal affective disorder or subsyndromal seasonal affective disorder, as defined by the questionnaire, and the frequency of major depressive disorder; of the 15 depressed bulimic patients, five (33%) met criteria for seasonal affective disorder or subsyndromal seasonal affective disorder, while six (37.5%) of the nondepressed bulimic patients met these criteria.

*Meteorological measures.* The meteorological measures of dark hours, hours of bright sunshine, global solar radiation, and temperature per month were highly intercorrelated. Dark hours were significantly negatively associated with global solar radiation (r=–0.99, df=12, p<0.001), hours of bright sunshine (r=–0.97, df=12, p<0.001), and temperature (r=–0.86, df=12, p<0.001) but not precipitation (r=–0.32, df=12, n.s.). Hours of bright sunshine were correlated with global solar radiation (r=0.97, df=12, p<0.001) and temperature (r=0.87, df=12, p<0.001) but not precipitation (r=0.40, df=12, n.s.). Global solar radiation was correlated with temperature (r=0.81, df=12, p<0.001) but not precipitation (r=0.29, df=12, n.s.). Precipitation was associated with temperature (r=0.62, df=12, p<0.05). Precipitation did not exhibit significant associations with bulimic symptoms. Since the remaining meteorological measures were so highly intercorrelated (and each was significantly associated with bulimic symptoms), their independent effects on the behavioral measures could not be adequately assessed. The measure of dark hours was therefore employed as a proxy variable for a class of measures representing availability of light and temperature. The measure of dark hours was selected because it correlated most highly with

**FIGURE 1. Seasonal Variations[a] in Binge Eating, Purging, and Feeling Worst Among 31 Bulimic and 31 Comparison Subjects**



[a]Binge eating, purging, and feeling worst were determined according to the modified Seasonal Pattern Assessment Questionnaire. Number of dark hours was defined as 24 hours minus the average photoperiod for each month.

[b]A significant group effect (F=103.99, df=1, 60, p<0.001), month effect (F=9.91, df=11, 50, p<0.001), and Group by Month interaction (F=7.06, df=11, 50, p<0.001) were found. The correlation between number of dark hours and likelihood of binge eating was significant (r=0.97, df=12, p<0.001).

[c]A significant group effect (F=83.77, df=1, 60, p<0.001), month effect (F=3.99, df=11, 50, p<0.001), and Group by Month interaction (F=2.76, df=11, 50, p<0.007) were found. The correlation between number of dark hours and likelihood of purging was significant (r=0.94, df=12, p<0.001).

[d]A significant group effect (F=6.46, df=1, 60, p<0.02) and Group by Month interaction (F=2.50, df=11, 50, p<0.02) were found. The correlation between number of dark hours and likelihood of feeling worst was significant (r=0.92, df=12, p<0.001).

binge eating and purging and because photoperiod has been previously linked to seasonal changes in mood in seasonal affective disorder (18).

*Seasonality of bulimic symptoms.* Seasonal variations in binge eating, purging, and mood are presented in figure 1 for the bulimia nervosa and normal comparison groups. Also displayed are the dark hours for each month. As expected, the ANOVA revealed a significant group effect (F=103.99, df=1, 60, p<0.001) for binge eating (figure 1, top left). The post hoc multiple comparisons, with the Bonferroni correction, revealed that for every month except the summer months of May, June, July, and August, bulimic patients binged more frequently than those in the comparison group. There were also significant effects of month (F=9.91, df=11, 50, p<0.001) and Group by Month interaction (F=7.06, df=11, 50, p<0.001) on binge frequency. Examination of the interaction effect revealed that the monthly variation in binge eating was far stronger in the bulimic group than in the comparison group.

Effects on purging were similar. Because there was very little purging reported among the normal comparison group, the bulimia nervosa group reported a greater likelihood of purging across all months (F=83.77, df=1, 60, p<0.001) and, among the post hoc comparisons with the Bonferroni correction, for each individual month. Significant effects of month (F=3.99, df=11, 50, p<0.001) and the Group by Month interaction (F=2.76, df=11, 50, p<0.007) were also found. Not surprisingly, examination of the interaction revealed a far stronger monthly variation in purging for bulimic patients than for those in the comparison group.

The item from the Seasonal Pattern Assessment Questionnaire most frequently used to examine seasonal effects on mood is the item that addresses the time of the year when the subject "feels worst." In this case both the bulimia nervosa and normal comparison groups exhibited seasonal effects (figure 1, bottom left). The ANOVA indicated a significant group (bulimic versus comparison group) effect (F=6.46, df=1, 60, p<0.02) and a significant Group by Month interaction (F=2.50, df=11, 50, p<0.02). The results of the t tests indicated that while the bulimia nervosa group reported feeling worst more than did the normal comparison group, this difference did not achieve statistical significance for any particular month after the Bonferroni correction for multiple comparisons was applied.

*Meteorological effects on behavioral measures.* The influence of dark hours on the proportion of subjects who reported binge eating in each month is displayed in figure 1 (top right). Dark hours significantly predicted the proportion of subjects who reported binge eating in each month (r=0.97, df=12, p<0.001). A time series cross-correlation analysis (between binge eating and dark hours) was conducted at monthly lags of from 0 to 5 in order to evaluate 1) time delays and 2) periodicity of the association (table 2). The 0 lag correlation was highest, indicating that monthly changes in binge eating were best predicted by the dark hours within the current month (rather than previous months). The maximal reversal of the correlation was obtained at a lag of 5, indicating a 12-month cycle.

A similar pattern was observed for the correlation of photoperiod and purging (figure 1, middle right). In this case, the 0 lag correlation (r=0.94, df=12, p<0.001) was again the highest, and the maximal reversal of the correlation occurred at a lag of –5. Photoperiod also strongly predicted the likelihood of feeling worst each month. The 0 lag correlation (r=0.92, df=12, p<0.001) was also the highest, with the highest reversal at a lag of 4.

A quadratic equation significantly explained the monthly variation in photoperiod ($R^2$=0.90, df=12,

**TABLE 2. Cross-Correlation Analysis of Binge Eating, Purging, and Feeling Worst With Photoperiod Among the Subjects With Bulimia Nervosa in Study 1**

| | Lag (months)[a] | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Item | –6 | –5 | –4 | –3 | –2 | –1 | 0 | 1 | 2 | 3 | 4 | 5 |
| Binge | –0.52 | –0.58 | –0.39 | 0.03 | 0.40 | 0.78 | 0.97 | 0.63 | 0.14 | –0.30 | –0.51 | –0.57 |
| Purge | –0.54 | –0.64 | –0.41 | 0.01 | 0.40 | 0.76 | 0.94 | 0.62 | 0.12 | –0.29 | –0.51 | –0.56 |
| Feel worst | –0.56 | –0.52 | –0.32 | 0.05 | 0.45 | 0.80 | 0.92 | 0.56 | 0.06 | –0.41 | –0.64 | –0.60 |

[a] The lag (in months) represents the number of months the photoperiod data are shifted when the correlations with self-report items are calculated. A lag of 0 means that the January photoperiod data are lined up with the January self-report item, February with February, etc., for all 12 months. A correlation at –1 month lag is the result of associating December photoperiod with January self reports, January with February, etc. This is repeated until all possible lagged correlations are obtained.

$p<0.001$), as well as in reported binge eating ($R^2=0.90$, df=12, $p<0.001$), purging ($R^2=80$, df=12, $p<0.01$), and mood ($R^2=0.77$, df=12, $p<0.01$) among the bulimia nervosa group, and in binge eating ($R^2=0.62$, df=12, $p<0.01$) and mood ($R^2=0.52$, df=12, $p<0.01$) among the normal comparison group.

*Seasonality of Seasonal Pattern Assessment Questionnaire behavioral measures.* ANOVAs revealed significant monthly variations (across both bulimic and comparison groups) for the remaining nine behavioral/emotional items listed in section 3 (months most affected) of the Seasonal Pattern Assessment Questionnaire. Both groups reported significant monthly fluctuations in their likelihood to eat most, eat least, socialize most, socialize least, gain weight, lose weight, sleep most, sleep least, and feel best (results for feel worst were reported earlier in this article). Bulimic patients were more likely than those in the comparison group to report being most likely to gain weight ($F=4.03$, df=1, 60, $p<0.05$) and most likely to eat most ($F=9.32$, df=1, 60, $p<0.003$) across months. There was also an effect of the interaction of group and month on reported likelihood of eating most; this effect was of marginal significance ($F=1.86$, df=11, 50, $p<0.07$). The only months during which bulimic patients were significantly more likely than those in the comparison group to report eating most (after the Bonferroni correction was applied) were November ($t=2.94$, df=60, $p<0.005$) and February ($t=4.39$, df=60, $p<0.001$). In both groups the highest proportion of subjects reported that they ate most in December (81% [N=25] of bulimic patients and 68% [N=21] of comparison subjects).

These results indicate that significant monthly patterns in weight fluctuation and eating were experienced by both bulimic patients and comparison subjects. Compared to the normal comparison group, the patients with bulimia nervosa reported greater seasonal increases in weight and eating during late fall and winter.

*Degree of change in Seasonal Pattern Assessment Questionnaire seasonal symptoms.* Multivariate ANOVAs revealed that bulimic patients reported a significantly stronger degree of seasonal change than did comparison subjects in the six symptoms addressed in section 2 (degree of change in seasonal affective disorder symptoms) of the questionnaire ($F=2.778$, df=6, 55, $p<0.02$). Post hoc univariate analyses that used the Bonferroni correction revealed that bulimic patients reported a stronger degree of seasonal change in sleep ($F=7.83$, df=1, 60, $p<0.007$), mood ($F=8.41$, df=1, 60, $p<0.005$), weight ($F=12.07$, df=1, 60, $p<0.001$), and energy ($F=7.90$, df=1, 60, $p<0.007$) than did the comparison group.

## STUDY 2

### *Method*

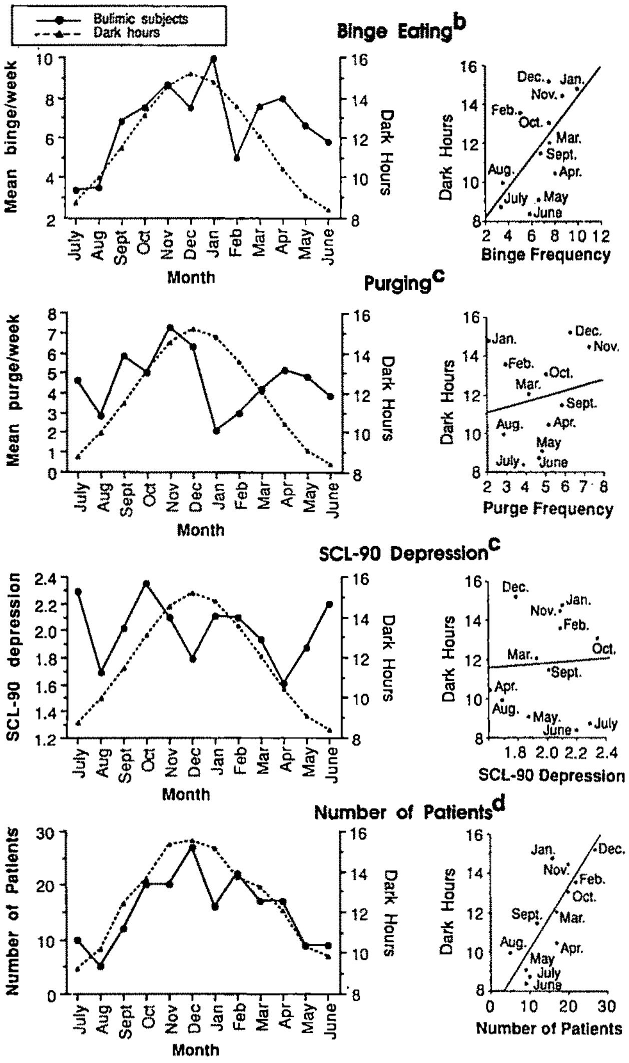
*Subjects.* The subjects in this study were 197 patients from the eating disorders clinic who met *DSM-III* criteria (182 patients) or *DSM-III-R* criteria (15 patients) for bulimia or bulimia nervosa. They were selected for this study, on the basis of this diagnosis, from 345 consecutively referred patients who were assessed between 1984 and 1988. Of the 197 subjects, 193 were women and four were men. The diagnosis of bulimia or bulimia nervosa was based on subjects' responses to the DIS (12) in the case of bulimia, or to the revised version of the DIS (DIS-R) in the case of bulimia nervosa. The diagnosis was confirmed by clinical interview and was supported by subjects' responses to the Eating Disorders Inventory (14) and Diagnostic Schedule for Eating Disorders (13).

*Procedure.* As part of the standard assessment procedure in the eating disorders clinic, subjects completed a self-report questionnaire regarding frequency of binge eating and vomiting in the previous week. They also completed the 90-item Symptom Checklist-Revised (SCL-90-R) (19), the Eating Disorders Inventory, Diagnostic Schedule for Eating Disorders, and either the DIS or DIS-R. Date of assessment and date of birth were recorded for every subject. Environmental data for mean monthly temperature, hours of bright sunshine, global solar radiation, and dark hours were gathered, as described in study 1. Again, because of very high intercorrelations, the measure of dark hours was used as the proxy variable representing temperature, global solar radiation, and hours of sunshine.

### *Results*

*Group characteristics.* The 197 bulimic subjects had a mean age of 26 years, an average weight of 134 lb, and an average height of 5 ft 4 in. They reported binge eating an average of 7.3 times per week, self-induced vomiting

FIGURE 2. Seasonal Variations[a] in Binge Eating, Purging, Depression, and Number of Patients Among 197 Bulimic Subjects



[a]Binge eating and purging were defined on the basis of patients' self-reports of symptom frequency. Depression was defined as the raw score obtained on the SCL-90 depression subscale. Number of dark hours was defined as 24 hours minus the average photoperiod for each month.

[b]Binge eating frequency was significantly correlated with number of dark hours ($r=0.63$, $df=12$, $p<0.03$).

[c]No significant correlation with dark hours was found.

[d]Number of new patients seen in the clinic who met *DSM-III* criteria for bulimia was correlated significantly with number of dark hours ($r=0.86$, $df=12$, $p<0.001$).

an average of 5.0 times per week, and an average of 6.5 total purge episodes (including laxative use) per week. Thirty-five percent (N=69) of the group met *DSM-III* criteria for recurrent major depression, while 61.9% (N=122) met criteria for a lifetime diagnosis of affective disorder (i.e., major depressive episode: 53.2% [N=65], dysthymic disorder: 27.1% [N=33], atypical bipolar disorder: 12.8% [N=16]). The average SCL-90-R depression score of 2.03 represented a T score of 69 based on norms for nonpatient women. A lifetime diagnosis of anorexia nervosa (according to subjects' responses to the DIS) was made for 7.5% of the subjects.

*Seasonality of symptoms.* Mean binge frequency reported by each subject at the time of the initial assessment was significantly correlated with dark hours in the month of the assessment ($r=0.63$, $N=12$, $p<0.03$) (figure 2, top left and right). However, mean purge frequency and mean SCL-90-R depression scores were not significantly related to the environmental variables of dark hours (figure 2), hours of bright sunshine, temperature, or global solar radiation. There were no significant relationships between month of birth and frequency of binge eating, frequency of purging, or depression score. The number of patients who met *DSM-III* criteria for bulimia, who presented to the clinic by month, correlated significantly with monthly dark hours ($r=0.86$, $N=12$, $p<0.001$) (figure 2, bottom). A quadratic equation significantly predicted binge frequency ($R^2=0.59$, $df=12$, $p<0.01$) but not purge frequency or SCL-90-R depression score. Nonetheless, binge frequency and purge frequency were significantly correlated ($r=0.67$, $df=196$, $0<0.001$).

## DISCUSSION

It has been reported that a large percentage of the population shows seasonal changes in mood, energy, and appetite and that among a subgroup, these symptoms are sufficiently severe in the winter months to be considered a seasonal affective disorder (3, 4, 19–21). The present study indicates that seasonal changes also have a strong influence in bulimia nervosa. Using methods similar to those employed in previous studies of normal subjects and patients with seasonal affective disorder, we found that the retrospective self-reports of patients with bulimia nervosa indicate a far greater perceived likelihood of binge eating and purging during the winter than summer months. In addition, a cross-sectional analysis of patients with bulimia nervosa who presented to a clinic specializing in eating disorders also indicates that actual binge frequency varies seasonally, with greater binge frequency during the winter.

It is striking that seasonal binge eating, as assessed by the modified Seasonal Pattern Assessment Questionnaire in the present study, exhibits a monthly curve that is almost identical to that obtained from plotting dark hours, or the inverted curve of photoperiod. The high correlation (0.97) between binge eating and dark hours reflected a stable linear relationship over the entire 12 months of the year. Similar high correlations have been reported between mood and photoperiod among patients with seasonal affective disorder (3, 22). In each case, the associations have been based on retrospective self-reports that used the Seasonal Pattern Assessment Questionnaire. We recognized that this method may elevate the association, for several reasons. First, there is the problem of correlated error inherent in an instrument like the Seasonal Pattern Assessment Questionnaire. With this method, assessment of a single month is not independent of other months, and a tendency to cluster monthly reports may artificially elevate the strength of the association. Second, individuals may recall greater seasonal variation than actually exists. Third, the data from the modified questionnaire are based on the percentage of individuals who report that a given month is one of the months in which they are most likely to binge eat, but the data do not reflect the frequency of binge eating. The cross-sectional data addressing binge frequency among bulimic patients assessed in the clinic during different months of the year are therefore important, since the results support the finding that monthly binge eating is strongly associated with shorter photoperiod (or more dark hours), even when data for each month are collected independently.

This effect also appears to be significant clinically, since the number of patients presenting to the clinic who meet *DSM-III* criteria for bulimia was also significantly associated with photoperiod. It is unlikely that this effect is the result of seasonal changes in referral frequency or staff vacations, since the clinic is booked to see four new patients per week year round and maintains a waiting list of at least 2 to 4 weeks throughout the year. The only exception to this rule is that the clinic typically closes for 1 week in December for Christmas, but that was a month in which a peak number of patients met *DSM-III* criteria for bulimia. Since the number of appointments available per week remains relatively stable year round, the seasonal variation in number of patients with bulimia nervosa appears to be due to the fact that fewer of those seen in the summer actually meet the criteria for the disorder. This may reflect a seasonal variation in severity of the disorder, as suggested by the binge frequency data, although we cannot rule out other possible explanations for a selective seasonal predisposition for patients with bulimia nervosa to attend a clinic.

Since photoperiod is so highly correlated with the other climatic and meteorological variables, the independent effect of these variables cannot be adequately estimated. Statistical techniques such as covariance are limited in this case. Photoperiod was therefore used as a proxy variable representing wide-ranging climatic and meteorological change throughout the year. It is reasonable to suggest, however, that photoperiod, or, more specifically, availability of light, is associated with these effects because seasonal symptoms in patients with seasonal affective disorder can be reversed by phototherapy (22, 23). It remains to be determined whether phototherapy is effective in bulimia nervosa, and we are currently investigating this. To date, at least one published case report suggests that it may be effective (24).

In the present study a higher percentage of patients with bulimia nervosa than of normal comparison subjects met Seasonal Pattern Assessment Questionnaire criteria for syndromal and subsyndromal seasonal affective disorder. The rate of seasonal affective disorder in bulimia nervosa did not, however, approach the rate reported for affective disorders in bulimia nervosa, which has been estimated to be as high as 70%–80% (25, 26). Furthermore, the depression typically reported in bulimia nervosa was not found to be associated with the syndromal and subsyndromal seasonal affective disorder reported by patients with bulimia nervosa in this study. The high levels of depression consistently reported in bulimia nervosa cannot be accounted for by seasonal affective disorder, according to the results of the present study. In fact, the results lend themselves to the interpretation that the seasonal effects on bulimic symptoms may be independent of the effects on depressive symptoms. Consistent with the observations of Fonari et al. (1), the present study found that patients with bulimia nervosa report greater seasonal variation in weight gain and eating than do normal comparison subjects. Differences in the seasonal effects on mood were less pronounced. The peak periods of low mood from November through February were no different for bulimic patients than for comparison subjects. When depressive symptoms were examined by using the SCL-90-R in a cross-sectional design, no seasonal effects were obtained. The SCL-90-R has been reported to be sensitive to changes in depression. It has been demonstrated to be highly sensitive to both neurovegetative and cognitive symptoms of depression (19), correctly classifies over 70% of women assessed for depression according to the Feighner criteria (27), and shows a high degree of sensitivity in patients with varying durations of depressive illness (from 1 week to over 1 year) (28).

The self-report of feeling worst cannot, therefore, be compared to the more clinically relevant measurement of depression offered by the SCL-90-R. Rather, self-reports of feeling worst are most likely to reflect a nonspecific state of dysphoria. The major difference between the bulimia nervosa and comparison groups in terms of seasonal variation was in the areas of binge eating, food intake, and weight, not in depression. Patients with bulimia nervosa therefore appear to be more sensitive to the food intake regulation effects than to the affective impact of seasonal change; previous research suggests that the reverse appears to be true for patients with seasonal affective disorder (2–4).

The close associations of food intake, bulimic symptoms, and seasonal change in bulimia nervosa may be linked to central serotonin activity. That serotonergic mechanisms may be altered in bulimia nervosa has been based on several lines of evidence (29). Kaye et al. (30) have reported low levels of 5-hydroxyindoleacetic acid (5-HIAA) in the CSF of bulimic anorexic patients after weight recovery. Lower CSF 5-HIAA levels have been reported in patients with bulimia nervosa who binge more than two times per day than among less symptomatic patients with bulimia nervosa and comparison subjects (31). Altered peripheral serotonin uptake (32) has been reported, as well as blunted prolactin response to m-chlorophenylpiperazine (33). Bulimia nervosa patients have been reported to reduce binge eating in response to the serotonergic agonists fluoxetine (7) and fenfluramine (8, 34).

That central serotonergic mechanisms may mediate the reported seasonal effects in bulimia nervosa is indirectly supported by Carlsson et al. (35), who have found that hypothalamic serotonin levels (post-mortem analysis of a nonpsychiatric population) are lowest in December through January and rise throughout the rest of the year until peak levels are observed in October through November. Platelet serotonergic uptake also follows a seasonal pattern, with highest levels in the spring and lowest levels in the fall (36). O'Rourke et al. (9, 10) have demonstrated that *d*-fenfluramine is effective in seasonal affective disorder, suggesting that sensitivity to seasonal variations in serotonin levels may be common to both bulimia nervosa and seasonal affective disorder.

The effect of serotonin on binge behavior in bulimia nervosa may be closely associated with the regulation of serotonergic food intake mechanisms. One effect of serotonergic agonists, such as fenfluramine and fluoxetine, for example, is to reduce meal size and rate of food consumption (37). This may be the mechanism by which binge behavior is reduced in bulimia nervosa. Other agents, such as the antidepressants desipramine and imipramine, are also effective in bulimia nervosa (38–40), although probably not because of activation of serotonergic mechanisms. Previously we reported that patients with bulimia nervosa who respond to desipramine have a higher purge frequency and lower urge to binge than do nonresponders (41). The clinical effects of noradrenergic antidepressants may therefore arise from mechanisms that are pharmacologically and behaviorally different from those of serotonergic agonists. Consistent with this notion was the observation that binge eating and purging were dissociated to a degree in study 2. Although there was a correlation, less than 50% of the variance in binge behavior was shared by purge behavior. While binge eating peaked in January, that was the month of lowest purge frequency. Similarly, measures of clinical depression did not vary seasonally, but binge behavior did. Separate biological and psychological processes may therefore be associated with discrete components of bulimic behavior.

In summary, binge eating exhibits marked seasonal patterns in bulimia nervosa, with binge eating being more frequent during seasons characterized by low levels of available light. Dysphoria (but not depression) may also vary seasonally, and there is a higher than normal rate of seasonal affective disorder and subsyndromal seasonal affective disorder in bulimia nervosa. The number of patients presenting to an outpatient eating disorders clinic who met strict *DSM-III* criteria for bulimia was highly related to seasonal changes in photoperiod. The seasonal variation in bulimia nervosa appears to be a primary effect on binge eating, rather than on purge behavior or depression. It is speculated that the seasonal effects are mediated through seasonal variations in central serotonergic mechanisms.

Bonnie Bruce, R.D., Mark Perl, M.D., and Lorrin M. Koran, M.D.

Objective: *This study examined the relative effectiveness of desipramine, cognitive-behavioral therapy, and their combination in the treatment of bulimia nervosa, together with the effects of withdrawing medication after two different lengths of treatment.* Method: *Seventy-one patients meeting* DSM-III-R *criteria for bulimia nervosa, recruited from an eating disorders clinic or by advertisements, were assigned at random to one of five groups: desipramine (withdrawn at 16 or 24 weeks), combined treatment (medication withdrawn at 16 or 24 weeks), and cognitive-behavioral therapy (15 sessions). All treatments were conducted individually in an outpatient clinic. The primary outcome measures were binge eating and purging rates assessed at pretreatment, 16, 24, and 32 weeks. The results were analyzed as three groups (medication, cognitive-behavioral therapy, and combined treatment) at 16 weeks and as five groups at subsequent assessments.* Results: *At 16 weeks, both cognitive-behavioral therapy and the combined treatment were superior to medication given for 16 weeks in reducing binge eating and purging. At 32 weeks, however, only the combined 24-week treatment was superior to medication given for 16 weeks. The combined treatment was also more effective in reducing dietary preoccupation and hunger. Continuing cognitive-behavioral therapy appeared to prevent relapse in patients withdrawn from medication at 16 weeks.* Conclusions: *Overall, the results favor the use of a combination of medication and cognitive-behavioral therapy in the treatment of bulimia nervosa, with medication continued for at least 24 weeks.*

(Am J Psychiatry 1992; 149:82–87)

Two approaches to the treatment of bulimia nervosa, antidepressant medication and variants of cognitive-behavioral therapy, have been shown to be effective in controlled trials (1–3). Imipramine (4, 5), desipramine (6), phenelzine (7, 8), bupropion (9), and fluoxetine (10) have all been found useful. Those receiving active treatment in controlled medication studies reduced their purging by an average of 71%, and 35% of participants stopped purging (3). Dropout rates ranged from 0% to 33% for those receiving active medication. Thus, antidepressant treatment appears promising, although there are some indications that the relapse rate may be significant both while medication is continued and after its withdrawal (11, 12). Neither the extent of relapse after withdrawal from medication nor the differential response to varying durations of antidepressant treatment has been studied in a randomized withdrawal design.

Controlled trials of variants of cognitive-behavioral therapy for bulimia nervosa have been conducted both in individual and group formats (3). Purging was reduced by an average of 77%, with 38% of patients becoming abstinent in the published controlled studies (3). Dropout rates ranged from 0% to 34% for those receiving cognitive-behavioral therapy. These results appear comparable to those of antidepressant treatment, setting the stage for a study comparing the effectiveness of medication and psychological treatments.

To date, only one study has compared the two treatments and their combination (13). In that study, patients with bulimia nervosa were randomly assigned to one of four groups: imipramine, placebo, imipramine combined with group psychotherapy, and placebo combined with group psychotherapy. Group psychotherapy included many of the procedures of cognitive-behavioral therapy, as well as therapist-supervised practice in eating. All three

active treatments were superior to placebo in reducing binge eating and purging. Group psychotherapy was superior to medication alone. Antidepressant treatment did not add to group psychotherapy in terms of normalizing eating behavior, but it did lead to greater reductions in measures of depression and anxiety.

The present study was designed to investigate three main questions: 1) Which treatment would prove most successful: desipramine, cognitive-behavioral treatment, or their combination? 2) Is there an advantage for prolonged medication treatment? 3) Does continued cognitive-behavioral therapy protect against relapse after discontinuation of medication?

## METHOD

### *Subjects*

Participants were recruited from patients being evaluated in a university eating disorders clinic and by means of advertisements in the local media. After initial telephone screening, eligible subjects were interviewed by staff psychologists or psychiatrists. At this interview the study was described in detail to the potential participant, and informed consent was obtained. A semistructured interview was then completed to ensure that participants met the entry criteria. Criteria for participation included the following: women aged 18–65 years who met *DSM-III-R* criteria for bulimia nervosa, had no concurrent medical condition that would preclude the use of antidepressants, and had no evidence of conduction disturbance on electrocardiography. Exclusion criteria included current anorexia nervosa, drug or alcohol abuse, psychosis, or depression with suicidal risk of sufficient severity to preclude the use of antidepressants on an outpatient basis.

One hundred interviews of potential subjects yielded 71 individuals who participated in the study. Eleven potential participants met an exclusion criterion, and 18 did not wish to continue in the study. Subjects were assigned at random to one of five groups: desipramine continued for 16 or 24 weeks, individual cognitive-behavioral therapy, or the combined treatment with medication continued for either 16 or 24 weeks. Participants were told of their randomization, including the week of medication withdrawal, at the first treatment session.

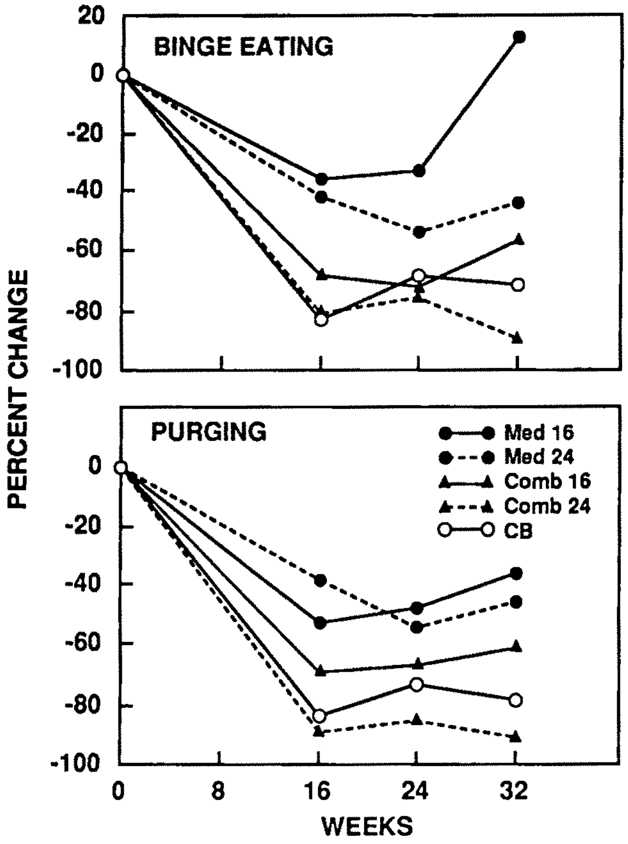
The mean±SD age of the participants was 29.6±8.9 years. Thirty-two percent were married, 56.3% were single, and the remainder were either divorced (8.5%) or separated (2.8%). Fifty-six percent had completed college, 36.7% had completed some college, and the remainder had either completed high school (5.6%) or completed some high school (1.4%); 83% were employed at the time of the study. Binge eating had begun at 19.9±5.7 years of age and purging a few months later at 20.7±5.9 years of age. The participants reported an ideal weight of 53.7±5.8 kg; their weight as measured at baseline was 59.9±9.1 kg. Frequency of purging and binge eating before treatment was 9.2±6.9 times per week and 7.5±5.7 times per week, respectively. Twenty-two percent had been diagnosed as having anorexia nervosa in the past.

### *Procedure*

Medication treatment was guided by a standard protocol detailed in a manual. This treatment was administered by one of the study psychiatrists in sessions averaging 15 minutes. The three study psychiatrists had all had more than 10 years' experience in prescribing antidepressant medication. No psychotherapeutic treatment was given in this condition. The rationale given to patients was that medication had been shown in a significant number of well-controlled studies to stop or decrease binge eating and purging. Participants were given 25 mg of desipramine hydrochloride for the first 3 days, after which the dose was increased to 50 mg. The dose was then increased by 50-mg increments every 3 to 5 days to a maximum of 300 mg, depending on response to treatment and side effects. At 6 weeks, serum levels of antidepressant were obtained and provided to the treating psychiatrist, who used this information to increase or decrease (in the case of toxic levels) the medication dose. At this stage of treatment a maximum of 350 mg of desipramine was allowed. Participants were seen weekly for the first 4 weeks of treatment and then at weeks 6, 8, 12, and 16 for those withdrawn at 16 weeks; those continuing the medication were, in addition, seen at weeks 18, 20, and 24. Medication was withdrawn gradually, usually being completed in 2 weeks, and participants were then seen for two further sessions at 2-week intervals. Thus, those withdrawn at 16 weeks completed their treatment contacts at week 20, while those withdrawn at 24 weeks completed their treatment contacts at week 28.

Cognitive-behavioral treatment was administered individually in 50-minute sessions by Ph.D.-level psychologists with at least 5 years' experience in treating patients with bulimia nervosa. Since a treatment manual is available, the treatment will be briefly described here. (The treatment manual for cognitive-behavioral therapy is available from Dr. Agras; please enclose a check for $10 to cover production and handling costs.) The rationale given for treatment was that social pressure for a thin body leads some women to diet and that the subsequent food deprivation then leads to binge eating, followed by purging in an attempt to control weight. When dietary restraint is reduced, this pattern can be gradually broken. The core treatment procedures included self-monitoring of food intake, binge eating and its circumstances, and purging. In the first part of therapy these data were used to encourage the consumption of three or more well-balanced meals each day. Patients were also encouraged to consume increasing amounts of their feared and avoided foods by adding them to meals. Throughout treatment, cognitive restructuring was used to correct distorted cognitions, for example, rigid food rules and body image concerns. In the last part of therapy, relapse prevention strategies

**FIGURE 1. Change in Binge Eating and Purging Behavior of Patients With Bulimia Nervosa Treated With Medication, Cognitive-Behavioral Therapy (CB), or a Combination**



were used. Participants in this condition received 15 sessions of treatment over the first 16 weeks of the study and were seen in follow-up sessions at weeks 20, 24, and 28.

Weekly meetings were held with the therapists to supervise the medication and psychosocial treatments and to ensure adherence to the study protocol. In addition, randomly selected tape recordings of sessions were audited to ensure that the specific procedures described in the treatment manual were used. Ninety-five percent of the audited tapes included all the procedures described in the manual for that session.

### *Assessments*

Measures were obtained by an assessor who was blind to the participants' treatment assignment. Since binge eating and purging are private behaviors, the primary measures in this study were the frequencies of binge eating and purging, collected by 7-day recall. Other potentially more objective methods, such as serum amylase levels (14) and glycosylated hemoglobin levels (15), have not proven useful. Secondary measures included the Beck Depression Inventory (16), Eating Disorders Inventory (17), Eating Attitudes Test (18), Three Factor Eating Questionnaire (19), Rosenberg Self-Esteem Questionnaire (20), self-efficacy in terms of confidence and ability to practice healthier eating behavior (21), and self-monitored mood states associated with binge eating. Assessments were completed before treatment and at 16, 24, and 32 weeks, although only the frequencies of binge eating and purging were collected at 32 weeks.

### *Data Analysis*

To select and reduce the secondary measures to be used in the final analysis, a principal components analysis of the secondary measures was undertaken. Five factors were found to have eigenvalues greater than 1 and accounted for 68.8% of the variance. The first factor, dietary preoccupation, accounted for 32.8% of the variance. The average of the Eating Attitudes Test dieting subscale and the Eating Disorders Inventory drive for thinness subscale, the subscales most highly correlated with this factor, was chosen to represent this factor. The second factor, mood fluctuation, accounted for 12.3% of the variance and was represented by the mean of the negative mood and urge to binge scores. The third factor, restraint, accounted for 9.6% of the variance and was represented by the cognitive restraint scale of the Three Factor Eating Questionnaire. The fourth factor, self-esteem, accounted for 7.9% of the variance and was represented by the Rosenberg self-esteem scale. The final factor accounted for 6% of the variance and included the disinhibition and hunger subscales of the Three Factor Eating Questionnaire. This factor was termed hunger-disinhibition. Each of these variables was subjected to a repeated measures analysis of covariance (ANCOVA) for the three groups (medication alone, cognitive-behavioral therapy, and the combined treatments) at 16 weeks by using baseline response as the covariate. Similarly, a repeated measures ANCOVA was carried out for five groups at 32 weeks for the primary measures and at 24 weeks for the secondary measures (which were not assessed at 32 weeks). A two-tailed level of significance was used throughout. When a significant Time by Group interaction was found, post hoc tests of the 10 possible pairwise comparisons were carried out. The Bonferroni correction was applied for these comparisons, resulting in an adjusted significance level of $p<0.005$. The primary analyses were conducted by intent to treat, i.e., regardless of whether the participant dropped out of treatment. However, in order to provide additional insights, secondary analyses were also done that included only subjects who completed treatment.

## RESULTS

There were no statistically significant differences between the three or five groups on the sociodemographic measures, the primary outcome measures, or the secondary measures at baseline assessment.

Data were not available for two subjects (2.8%) at the 16-week assessment, for three subjects (4.2%) at 24

[a] Medication withdrawn at 16 and 24 weeks.

weeks, and for five subjects (7.0%) at 32 weeks. Thus compliance with these assessments was excellent.

Of those assigned to receive medication, six participants (12.2%) had stopped medication by 6 weeks, seven (14.6%) by 16 weeks, and eight (17%) by 24 weeks. Reasons for stopping medication included side effects (seven subjects) and moving from the area (one subject). Of those assigned to receive cognitive-behavioral treatment, only one subject (4.3%) stopped treatment. Eighty-eight percent of subjects completed 70% of the cognitive-behavioral treatment sessions.

The mean dose of desipramine at 6 weeks was 168 mg, and at discontinuation of medication it was 167 mg. The mean serum level of desipramine at 6 weeks was 130.8 ng/ml. There were no significant differences between the groups in either medication dose or antidepressant blood levels.

The percent reduction in binge eating and purging for each of the five groups is shown in figure 1, and the mean values for the primary and significant secondary measures are given in table 1. At the 16-week assessment the combined treatment group had reduced purging by 80.9% (64% abstinent), while those receiving cognitive-behavioral treatment alone had reduced it by 82.6% (48% abstinent) and those receiving medication alone had reduced it by 42.7% (33% abstinent). Similar results were found for binge eating. The combined treatment group reduced binge eating by 82.6% (65% abstinent), the cognitive-behavioral group by 81.7% (50% abstinent), and the desipramine group by 38.8% (35% abstinent). There was a significant Time by Group interaction for purging ($F=6.35$, df=2, 65, $p<0.004$) and binge eating ($F=6.0$, df=2, 65, $p<0.005$). For purging post hoc analysis revealed that cognitive-behavioral therapy was superior to medication alone ($p<0.004$), as was the combined condition ($p<0.003$). Similarly, for binge eating both cognitive-behavioral therapy ($p<0.005$) and the combined condition ($p<0.004$) were superior to medication alone.

The analysis of binge eating and purging for the five groups over the 32 weeks of the study revealed a significant Time by Group interaction for both binge eating ($F=2.16$, df=12, 168, $p<0.02$) and purging ($F=2.13$, df=12, 168, $p<0.02$). In the case of purging, the 24-week combined treatment was superior to 16 weeks of medication ($p<0.005$). For binge eating the 24-week combined treatment was superior to medication given for both 16 ($p<0.004$) and 24 ($p<0.005$) weeks. Seventy percent of patients in the 24-week combined condition were then abstinent, compared with 55% for cognitive-behavioral therapy and 42% for 24 weeks of medication.

At 16 weeks there was a significant Time by Group interaction for dietary preoccupation ($F=4.53$, df=2, 62, $p<0.01$), with the combined group superior to the group receiving medication alone ($p<0.005$). At 24 weeks there was a significant Time by Group interaction for the hunger/disinhibition factor ($F=2.45$, df=8, 100, $p<0.02$). Post hoc tests revealed that the 24-week combined treatment was superior to cognitive-behavioral therapy ($p<0.005$).

There was no significant change in weight at either 16 or 24 weeks, with participants averaging a small (0.3 kg) loss in weight at both assessments. There were no significant differences between groups in terms of weight changes.

The intent to treat analyses described earlier in this paper were repeated and included only those participants who completed their respective therapies. The results were identical both for the initial ANCOVA and for the post hoc tests, with the following exception. At

16 weeks, no significant Time by Group interaction was found for the dietary preoccupation factor.

## DISCUSSION

Both the combined treatment and cognitive-behavioral therapy were superior to medication given for 16 weeks in reducing the primary symptoms of bulimia nervosa, namely, binge eating and purging. This finding is similar to that of Mitchell et al. (13), who used a placebo-controlled comparison. These researchers found that group psychotherapy based on cognitive-behavioral principles was superior to imipramine and that there were no differences between cognitive-behavioral treatment and the combined treatment in reducing binge eating and purging. In the present study, however, only the 24-week combined condition was superior to 16 weeks of medication at the 32-week assessment. In addition, the combined condition appeared to reduce associated psychopathology such as dietary preoccupation and hunger. Overall, then, the results of this study suggest that desipramine given for 24 weeks and combined with cognitive-behavioral therapy produces the broadest therapeutic benefits.

Interestingly, as shown in figure 1 and table 1, there was considerable relapse in binge eating for the group treated with medication for 16 weeks. The 24-week combined condition was superior to both the 16- and 24-week medication groups. This suggests that cognitive-behavioral therapy, if continued, may help prevent relapse after withdrawal of medication.

It is important to ascertain whether the effects obtained in this study are similar to those of other controlled studies of medication and cognitive-behavioral treatment. As noted earlier, the median rate of purging cessation after medication treatment in previously reported controlled studies was 35%, a rate exceeded by each of the medication groups in the present study. For cognitive-behavioral treatment, earlier controlled studies suggest an abstinence rate of 38%, while the abstinence rate in our study was 55%. The comparable figures from the Mitchell et al. study (13) were 16% for medication and 51% for group psychotherapy. Thus, the treatment results from the present study were comparable to those obtained in the previous research literature, suggesting that the comparisons between groups fairly represented the usual effects of treatment.

One limitation of this study was that the medication dose and blood levels achieved in this study, while within the therapeutic range, were somewhat low. Higher doses might have been associated with correspondingly better results. However, the abstinence rates achieved in the medication groups in the present study exceeded those of Mitchell et al. (13), who used a higher dose of imipramine and achieved higher blood levels. In addition, since only one medication was used in the present study, the results may not fairly represent what might be attained in clinical practice by using alternative medications for nonresponding patients. Similarly, given the effectiveness of other forms of psychosocial therapy in the treatment of bulimia nervosa, for example, response prevention of purging (22), focal psychotherapy (23), and interpersonal therapy (24), the use of one or more of these forms of treatment for the patient who did not respond to cognitive-behavioral therapy might have improved the results of psychosocial treatment. This question, which has not been investigated in bulimia nervosa, needs to be addressed in future clinical trials.

From a clinical viewpoint, the overall trend in the results of this study supports the use of the combination of medication and cognitive-behavioral treatment as the preferred therapeutic approach to bulimia nervosa, particularly when medication is continued for 24 weeks. These conclusions may, however, be tempered by the planned follow-up of these patients, which is still in progress.

# Multiple Personality Disorder in Switzerland

Jirí Modestin, M.D.

*Objective: There are no reliable data on the prevalence of multiple personality disorder. The objective of the study was to determine whether and, if so, how frequently patients with multiple personality disorder are encountered and diagnosed in Switzerland. Method: All qualified Swiss psychiatrists were sent a questionnaire on multiple personality disorder along with the* DSM-III *description of multiple personality disorder and three case examples. A total of 836 psychiatrists (66%) answered after two mailings, and 770 questionnaires qualified for evaluation. In addition, a random sample of nonresponders were contacted by telephone. Results: Three percent of the psychiatrists indicated that, at the time of the inquiry, they were treating or examining one or more patients who met* DSM-III *criteria for multiple personality disorder, and 10% indicated that they had seen multiple personality disorder at least once during their professional career. The patients were not equally distributed among the psychiatrists; three colleagues reported that they had seen much higher numbers of patients with multiple personality disorder. The point prevalence of multiple personality disorder among patients seen by psychiatrists in Switzerland amounts to 0.05%–0.1%. Conclusions: Multiple personality disorder appears to be a disorder that genuinely exists, even though it occurs relatively rarely.*

(Am J Psychiatry 1992; 149:88–92)

There is a jarring discontinuity in the number of reported patients with multiple personality disorder (1). A period of high interest in multiple personality disorder toward the end of the last century (2) was followed by a temporary disappearance of the syndrome (3) and a recent sharp increase in reports on multiple personality disorder (4), reaching almost "epidemic" proportions (5). The disorder has been accepted as a diagnostic entity by *DSM-III* and *DSM-III-R*, yet the views regarding its existence and frequency remain controversial; the waves of interest have been attributed to particular, time-linked circumstances (2, 6). Some clinicians, even those well acquainted with the disorder, have encountered few patients with multiple personality disorder during their long professional careers (7, 8), whereas others have come in contact with large series of patients with multiple personality disorder within several years (9, 10). The diagnosis of multiple personality disorder arouses strong feelings: 78% of therapists treating patients with multiple personality disorder encountered intense, half of them even extreme, skepticism in the form of deliberate interference with treatment on the part of their fellow professionals (11). Furthermore, the large majority of reports on multiple personality disorder originate in the United States. The diagnosis of multiple personality disorder may also be relatively frequent in some Dutch psychiatric facilities (12), but it has seldom been given in India (13) and only rarely in Great Britain (14).

There are virtually no reliable data on the prevalence of multiple personality disorder. The study of Bliss and Jeppsen (15) was rightly criticized because of their markedly biased sample (16). The estimate of Adityanjee et al. (13) was based on three patients with multiple personality disorder observed in a single institution. Two further estimates (17, 18) are not substantiated by any appropriate data. Ross (19, p. 90) indicated that multiple personality disorder had "a point prevalence of somewhere between 1 and 50 and 1 and 10,000 persons in urban North America." Again, his broad estimate was based on indirect, soft data. The existing uncertainty is accentuated by some American therapists' astronomically high probability of encountering patients with multiple personality disorder (6).

The present study was undertaken to help solve the perplexing situation. Its purpose was to determine 1) whether and, if so, how frequently patients with multiple personality disorder are encountered and diagnosed in Switzerland, 2) the proportion of Swiss psychiatrists

who diagnose multiple personality disorder, and 3) the distribution of the frequencies of multiple personality disorder diagnoses by individual psychiatrists.

## METHOD

In February 1989 a letter was sent to all qualified Swiss psychiatrists who were registered in the 1988 yearbook of Swiss physicians or whose names had been considered for the next edition. The letter explained the purpose of the study (to obtain information on whether and, if so, how frequently the diagnosis of multiple personality disorder has been made in Switzerland) and asked for cooperation. It contained the following:

1. A questionnaire asking for data on the professional activity of the psychiatrist, the frequency of his or her diagnosing multiple personality disorder, and some basic characteristics of the patients diagnosed as having multiple personality disorder, including their sex and date of birth. The latter data were requested in order to avoid counting any patient more than once.
2. A copy of the complete *DSM-III* text on multiple personality including the diagnostic criteria.
3. Three classic examples of patients with multiple personality disorder originally reported by Gmelin (in 1791), Azam (1887), and Hodgson (1891/1892) and reproduced in extenso later by Ellenberger (20).

The narrower *DSM-III* definition of multiple personality disorder was given preference in order to exclude questionable cases. Introducing the notion of personality states and accepting various degrees of sharing and commonalities between the personalities in nonclassic cases, the *DSM-III-R* criteria for multiple personality disorder seem to be less stringent and less precise. However, even the *DSM-III* criteria for multiple personality disorder are arbitrary and relatively unelaborated and leave much room for interpretation (16); the omission of amnesia, the "absolutely essential" criterion of multiple personality disorder (21) as a defining characteristic, is especially striking (6).

About 4 months after the letter, a second mailing was sent; it included the same complete set of information and was addressed to all those who had not yet answered. About another 4 months later an effort was made to reach a random sample (every fourth) of the nonresponders by telephone to obtain the pertinent information and to determine how representative the group of responders was of the whole population of Swiss psychiatrists.

## RESULTS

Of the 1,273 psychiatrists who received the questionnaire, a total of 836 (66%) responded after both mailings. Some colleagues did not fill out the questionnaire, the majority of them because they were no longer professionally active. A total of 770 (60%) questionnaires qualified for evaluation. Some questions remained unanswered in individual questionnaires, which explains the different number of responders for individual variables.

The 770 responding psychiatrists (566 [74%] men and 204 [26%] women) came from all parts of Switzerland and worked in all kinds of psychiatric facilities; 460 (62%) of them (N=741) were in private practice. The mean±SD duration of their professional activity (N=709) was 17.5±10.6 years. On average, a psychiatrist working in private practice or in a hospital (N=362) treated or was in charge of 65 patients at the time of this inquiry, whereas the corresponding caseload for a psychiatrist working in public services (N=187) was 98 patients.

The concept of multiple personality disorder had been (at least theoretically) previously known to 436 (61%) of the responding psychiatrists (N=710). The proportion of colleagues who had been acquainted with multiple personality disorder differed according to the setting in which they were working (N=684): private practice, 227 (52%) of 439; private inpatient settings, 16 (73%) of 22; public inpatient settings, 80 (73%) of 110; and public outpatient departments, 92 (81%) of 113 ($\chi^2$=43.20, df=3, p<0.0001). The psychiatrists who had or had not been acquainted with multiple personality disorder previously did not differ in regard to the length of their professional experience.

A total of 19 (3%) of the psychiatrists (N=679) indicated that they treated, were in charge of, or examined at the time of the inquiry patients they would diagnose as having multiple personality disorder according to the *DSM-III* criteria. Two of them had not previously been acquainted with the concept of multiple personality disorder, and four were not sure whether their diagnosis of multiple personality disorder was correct.

Altogether, 63 (10%) of the psychiatrists (N=655) indicated that they had seen at least one patient with multiple personality disorder during their professional career. Eight of them had not previously been acquainted with the concept of multiple personality disorder, and 17 had doubts regarding the diagnosis. The majority (46 of the 63 psychiatists) had seen one patient with multiple personality disorder; six reported having seen two patients, three reported having seen three, and two reported having seen four such patients. Each of the caseloads of five, six, and seven patients with multiple personality disorder was seen by one psychiatrist.

Three other psychiatrists were notable exceptions regarding the distribution of patients with multiple personality disorder. One colleague reported seeing two patients with multiple personality disorder at present and having seen 20 in the past; another colleague reported seeing one at present and 26 in the past, and the third reported seeing 20 at present and at least 59 in the past. These three psychiatrists were contacted. One of them said that she had seen videotapes on multiple personality disorder in the United States and had checked the patients carefully with regard to the symptoms in question; she admitted that *DSM-III* criteria for multiple personality disorder were possibly not met in all cases. I did not succeed in finding any special reason for the high frequency with which the two other colleagues (both men) encountered patients with multiple personality disorder. Both of them maintained that their patients conformed to the *DSM-III* criteria. Nevertheless, the one who diagnosed multiple personality disorder most frequently had not been acquainted with the clinical picture previously; this casts some doubt on his diagnostic reliability.

At the time of the inquiry, 44 patients were diagnosed as having multiple personality disorder by responding Swiss psychiatrists. If one takes into consideration the number of all the patients treated by these psychiatrists, the point prevalence of multiple personality disorder amounts to 0.11%; if the four doubtful cases and the 23 patients seen by the three psychiatrists mentioned earlier are excluded, the point prevalence amounts to 0.04%. If we consider only those patients diagnosed by psychiatrists with previous knowledge of multiple personality disorder, the corresponding point prevalences are 0.08% and 0.06%. Similarly, the responding psychiatrists indicated that during their entire professional careers, they had diagnosed 221 patients (primarily retrospectively) as having multiple personality disorder; this reduces the number of patients with multiple personality disorder to 71 if 22 doubtful cases and those seen by the three psychiatrists mentioned earlier are excluded. These figures indicate that 56 years or 174 years of professional experience, respectively, are needed to encounter one patient with multiple personality disorder. Again, if only patients diagnosed by psychiatrists with a previous knowledge of multiple personality disorder are included, the corresponding figures are 58 years or 121 years, respectively.

There were no differences between the psychiatrists who had ever diagnosed a patient as having multiple personality disorder and those who had not with regard to gender distribution or the part of the country and the kind of setting they worked in. On the other hand, those claiming to have met patients with multiple personality disorder had more frequently been acquainted with the concept of multiple personality disorder previously (50 [86%] of 58 versus 386 [59%] of 652; $\chi^2$=15.27, df=1, p<0.0001), had longer average professional experience (21 years versus 17 years; t=2.87, df=707, p=0.004 [two-tailed]), and had a higher average caseload in 1988 (321 patients versus 172 patients; t=2.72, df=561, p=0.007 [two-tailed]).

As indicated in 65 patients diagnosed as having multiple personality disorder, they were of both genders (33 [51%] were men and 32 [49%] were women), and their mean age at diagnosis was 38±15 years (range=14–74). With regard to the German-, French-, and Italian-speaking parts of the country, their distribution corresponded exactly with the proportion of responding psychiatrists. Thirty-eight (58%) of the patients were seen as outpatients, 23 (35%) as inpatients, and four (6%) in correctional facilities. Forty-eight (74%) were referred primarily for treatment, whereas 17 (26%) were referred for consultation or expert examination.

Of 101 nonresponders contacted by telephone, only 48 were ready to provide the information requested. The remaining psychiatrists no longer practiced, were not interested in the topic, or refused to cooperate without giving a reason. Among nonresponders there was a higher proportion of women (39 [39%] versus 204 [26%]; $\chi^2$=5.93, df=1, p=0.015), and all nonresponders who gave information worked in outpatient settings. There were no differences between responders and nonresponders with regard to the part of the country in which they practiced, whether they worked on a private or public basis, the duration of their professional activity, and their caseload. A smaller proportion of nonresponders had previously been acquainted with the concept of multiple personality disorder (17 [35%] of 48 versus 436 [61%] of 710; $\chi^2$=11.57, df=1, p<0.001). None of the psychiatrists responding on the telephone knew a patient with multiple personality disorder at the time of the inquiry, and only one psychiatrist reported having met a patient with a questionable diagnosis of multiple personality disorder in the past; these figures do not differ in statistical terms from those provided by the responders.

## DISCUSSION

A total of 66% of all Swiss certified psychiatrists returned the questionnaire, and over 90% of the questionnaires were eligible for evaluation. The majority (65%) of nonresponders had not been acquainted with the concept of multiple personality disorder previously, and, as indicated by some of them, this might have been one of the reasons for their nonresponse. Because only one past questionable case of multiple personality disorder could be identified among nonresponders, it seems improbable that unreported cases of diagnosed multiple personality disorder were missed in our survey.

At the time of the inquiry 3% of the responders reported *DSM-III*-defined cases of multiple personality disorder, and 10% had seen such cases during their professional career. Several factors, however, could have influenced these figures. Nonresponders may have seen patients with multiple personality disorder less frequently; the responders were not able to indicate the date of birth in all—mainly past—cases, so that some patients could have been counted more than once; and some patients with multiple personality disorder could have escaped the attention of the psychiatrists with no previous knowledge of the concept of multiple personality disorder. Nevertheless, the influences of these factors will be less pronounced regarding the data related to the time of the inquiry and besides, our proportion of 3% corresponds relatively well with the 4% reported by Ross et al. (22) from Canada. Our findings indicate the point prevalence of multiple personality disorder to be 0.05%–0.10% of patients seen by psychiatrists. Currently, this seems to be the most precise, data-based estimate of such a prevalence of multiple personality disorder; however, it may not be equally valid for other countries. In India, for example, the patients with the same "basic fault" are more likely to develop hysterical psychosis than multiple personality disorder (13), whereas the patients in the United States may more frequently develop multiple personality disorder because of, among other things, the presence of the well-known, media-popularized models and, perhaps, the higher frequency of child abuse.

The average age of our patients with multiple personality disorder at the time of the inquiry does not seem to differ considerably from that reported by others (23). In contrast, there is a clear difference regarding the female-to-male ratio, which was 8–9:1 in American series (5, 22–24) but about 1:1 in the present survey. We can only speculate about the reasons for this difference, pointing to the possible sociocultural influence or to the possibility of the nonhomogeneity of the population with multiple personality disorder (see later discussion). As recently reported (25), many cases of men with multiple personality disorder could have been missed in different studies, and the actual gender ratio may be closer to 1:1.

Three colleagues reported having seen an exceptionally high number of patients with multiple personality disorder. It is highly improbable that these three colleagues would be better diagnosticians or that multiple personality disorder would in some way concentrate in their practice, the more so because two of them indicated no special interest in multiple personality disorder and one of them had not even been acquainted with multiple personality disorder previously. Thus, the same phenomena must have been evaluated differently by these colleagues, or, conversely, the same diagnostic (*DSM-III*) criteria must have been interpreted and applied in a different way. Incidentally, the case of the Hillside strangler demonstrates the difficulties that even the most experienced experts have in diagnosing multiple personality disorder (6). The other possibility is that these colleagues have a different interview and therapy technique suitable to elicit or shape the symptoms in question. Patients with multiple personality disorder are excellent hypnotic subjects (26), and it is possible to suggest the formation of other personalities (27). Concentration on symptoms of multiple personality disorder is mandatory if a diagnosis is to be made because most of the patients with multiple personality disorder hide or deny their symptoms or are not aware of them (28); yet concentrating on symptoms may lead to their reinforcement and entrenchment (14). Experimental enacting of the multiple personality role is a relatively easy task (29).

Does this mean that multiple personality disorder is always an "iatrogenic, largely culture-bound, not naturally occurring symptom complex" (30)? My data do not support this hypothesis. Some well-known, highly distinguished, leading Swiss psychiatrists also reported having seen individual cases of multiple personality disorder. As expected in the case of rare events, the majority of psychiatrists saw no multiple personality disorder or only a very small number of cases. Those who reported patients with multiple personality disorder had been acquainted with the concept of multiple personality disorder more frequently in the past, had a slightly longer average professional experience, and also had a larger caseload. All these factors increase the probability of these psychiatrists seeing patients with multiple personality disorder. Thus, there apparently are patients with multiple personality disorder in Switzerland (even though I have personally never met one). The wide distribution of multiple personality disorder in time and space proves the disorder to be a genuine phenomenon (31).

Many colleagues indicated that they had frequently seen features of multiple personality disorder in their patients but that they had never seen a full picture of completely developed multiple personality disorder. Quite obviously, the tendency to split and to dissociate (more or less pronounced) is ubiquitous, and it finds its expression not only in many works of art (32) but also in many psychiatric concepts and theories (33–36). In some patients this ubiquitous tendency, together with their special individual history and sociocultural influences, will result in the "spontaneous" development of a "genuine" multiple personality disorder. In other patients, however, an iatrogenic influence and secondary gains seem to be probable. It is possible that women are overrepresented in the latter group of patients.

# Recovery and Major Depression: Factors Associated With Twelve-Month Outcome

Gabor I. Keitner, M.D., Christine E. Ryan, Ph.D.,
Ivan W. Miller, Ph.D., and William H. Norman, Ph.D.

---

*Objective: In spite of the prevalence and chronicity of major depression, there is no consensus regarding which clinical and psychosocial variables are associated with recovery. The authors examined the probability of recovery from a major depressive episode 12 months after hospital discharge, the factors most closely associated with recovery, and the patterns of improvement distinguishing patients who recovered from those who did not. Method: Seventy-eight inpatients with a* DSM-III *diagnosis of major depression were assessed at hospitalization and at monthly intervals for 12 months after discharge on a variety of clinical and psychosocial factors. Recovery status at 12-month follow-up was then used as a basis for comparing acute-phase patient characteristics and change in symptoms over time. Results: By the 12th month of follow-up, 34 (48.6%) of 70 patients met criteria for recovery. The five most important factors related to recovery were shorter length of hospital stay, older age at onset of depression, better family functioning, fewer than two previous hospitalizations, and absence of comorbid illness. The majority of patients who had recovered by 12 months had done so within 6 months of discharge; the average length of time to recovery was 4.9 months. Conclusions: Patients hospitalized for major depression have less than a 50-50 chance of recovering by 1 year. Some variables associated with nonrecovery (e.g., comorbid illness, poor family functioning) are amenable to clinical intervention; however, findings also suggest that there may be two distinct types of depressive illness with respect to recovery, one that remits quickly and the other with a more prolonged course of illness.*

(Am J Psychiatry 1992; 149:93–99)

---

Longitudinal studies of patients with major depression have reported similar rates (20%) of chronicity and of continuous well-being (1–3). Results of these studies provide long-term measures for the prognosis of major depression, but they are less useful in predicting short-term outcome or distinguishing a set of factors that may lead to chronicity or remission. Although studies suggest that 33%–53% of depressed patients are likely to recover within a year (4–7), there is no consensus regarding which clinical and psychosocial variables are associated with recovery.

For example, the relationship between severity of depression and recovery is unclear. There is evidence that a long duration of depression before treatment delays the recovery of some patients (8–11), but the effect of number of previous depressive episodes on outcome is equivocal (9, 10, 12–15). The relation of age at onset and age at index episode to recovery status is also inconsistent (14–17).

The relationship between psychosocial factors and prognosis is inconclusive. Family conflict and the absence of family support may predict poor outcomes for depressed patients, and patients with supportive families may have a better prognosis (7, 9, 18). Neither early loss (e.g., loss of a parent before the age of 20) nor recent life events are predictive of chronicity (19). It may be that recent stressful events rather than distant stressful events are related to relapse (20, 21).

Basic reasons for contradictions in reported effects may include variable diagnostic groupings within the samples studied, follow-up periods that range from as little as 3 months after discharge to greater than 10 years, and patients recruited from both inpatient and outpatient settings (17, 20).

In addition, variation in definitions of key concepts such as recovery and relapse, different boundaries used

for age cutoffs for age at onset, and a range of instruments measuring severity all contribute to differences in any conclusions that can be drawn from the available data. Furthermore, as several studies have shown, interpretation of variable effects often changes when significant bivariate relationships undergo further analysis with multivariate methods.

In this exploratory study we addressed some of these issues by focusing on the following questions: What is the probability of recovery from a major depressive episode by 12 months after hospital discharge? How do clinical and psychosocial factors contribute to the likelihood of recovery? and Is there any pattern that distinguishes patients who recover from those who do not?

## METHOD

### *Subjects*

The subjects were 78 patients with a diagnosis of major depression who were consecutively admitted to an acute-care university-affiliated hospital and who lived with at least one other family member. A trained research assistant administered the affective disorders section of the National Institute of Mental Health Diagnostic Interview Schedule (DIS) (22). Independent chart reviews by two experienced clinicians (G.I.K. and I.W.M.) confirmed that the diagnosis of major depression met *DSM-III* criteria and verified concurrent axis I, II, or III diagnoses.

Agreement on the diagnosis of major depression, the major focus of the study, was 87%, but we have no reliability data on ratings of comorbid illness. The research assistant conducted the DIS blind to chart diagnoses, and clinicians reviewed patient charts blind to the DIS assessment.

Sociodemographic, clinical, and psychosocial information was collected at the acute stage of hospitalization, at 6 and 12 months after hospital discharge, and at monthly intervals following discharge.

Seventy of the 78 patients completed the study. Two were lost to follow-up, two felt they no longer needed care, three refused, and one gave no reason. No apparent differences were found in baseline variables between patients who dropped out and those who remained in the study.

### *Measures*

Information recorded for patients and family members included age, sex, education, marital status, number of years married, household composition, occupation, and income. Socioeconomic status was determined by using the Nock-Rossi Index (23), a measure that uses characteristics of both husband and wife to derive a family's overall status.

Previous hospitalizations, suicidality, family and spouse history of psychiatric illness and alcoholism, and the presence of coexisting disorders were recorded for each patient. Following our standard procedure (24), we determined cortisol levels from blood samples obtained at 4:00 p.m. and 11:00 p.m.

The Modified Hamilton Rating Scale for Depression (25) was used to assess the severity of depression as well as the presence of depressive symptoms.

The DIS confirmed the diagnosis of major depression and provided age at onset of depression, longest previous episode, number of previous depressive episodes, and symptoms of dysthymia.

The Eysenck Personality Questionnaire (26) measured three aspects of personality characteristics: neuroticism, introversion, and psychoticism.

Patients and participating family members completed the Family Assessment Device, a measure of perceived family functioning derived from the McMaster Model of Family Functioning (27, 28).

Clinicians rated the family's functioning with the McMaster Clinical Rating Scale, an objective measure, analogous to the Family Assessment Device, that assesses families on several dimensions of functioning (unpublished paper of I.W. Miller et al.).

Each patient's premorbid family functioning was assessed by the patient's attending clinician on a 3-point scale on which 1=better than average and 3=worse than average.

The Global Adjustment Scale (GAS) (29) measured patients' overall functioning and was assessed on a monthly basis following discharge.

The Social Readjustment Rating Scale (30) was completed at the 6- and 12-month phases by an adult family member.

### *Procedure*

*Acute phase.* During the first week of hospitalization, after providing informed consent to participate in the study, hospitalized patients were given the DIS and the Modified Hamilton Rating Scale for Depression. At this time, patients and family members over 12 years of age completed the Family Assessment Device, and clinicians rated the family's functioning with the McMaster Clinical Rating Scale. The attending psychiatrist rated the family's premorbid functioning at the end of the patient's hospital stay, and the Eysenck Personality Questionnaire was completed during the later part of the patient's hospitalization.

*Follow-up.* On discharge from the hospital, patients were contacted by telephone on a monthly basis. A trained researcher administered the Modified Hamilton Rating Scale for Depression (minus the agitation and retardation items) and assessed the patient's overall functioning using the GAS. This follow-up procedure has been used successfully in previous studies of depressed patients to monitor the course of their illness (31).

In addition to the monthly interviews, patients and their families met with a clinician at 6 and 12 months after discharge. The Social Readjustment Rating Scale and family assessments were collected at these meetings.

This study was naturalistic by design. Although information was collected on treatments received, no attempt was made to influence the amount or type of therapy given to patients. In-hospital treatment and treatment after discharge included individual and family therapy as well as pharmacotherapy.

### *Analyses*

We defined recovery from a depressive episode as a Modified Hamilton Rating Scale for Depression rating of 7 or less for 3 consecutive months. Thus, the earliest possible time a patient could be considered recovered was at the third month after discharge. After recovery, if a patient scored 18 or more on the Modified Hamilton Rating Scale for Depression, he or she was considered relapsed.

Patients were grouped according to their recovery status at the 12th month after hospital discharge. Patients who met the criterion for recovery at 12 months were considered recovered. Patients who had not recovered or had relapsed (N=7), were considered not recovered. We then examined clinical, psychosocial, and family factors that had been collected during hospitalization to see if there were any relationships between acute-phase variables and outcome of depression at 12 months.

Chi-square statistics and t tests were used for bivariate analyses and logistic regression was used for the multivariate analyses in this exploratory study. The latter technique is advantageous when the outcome variable is dichotomous and predictor variables are a mix of discrete and continuous measures (32–35). Where a significant bivariate relationship existed, the factor was included in the multivariate analysis to see 1) whether the association still held and 2) which factors contributed most to a positive outcome. In each regression model used, the response variable was recovery status (0=no, 1=yes).

Although the number of statistical tests in the preliminary analyses may result in some factor being significant by chance, the exploratory nature of this study would argue against making alpha too stringent. However, we attempted to balance the analyses by conducting additional testing with multivariate methods. Also, the alpha value in the regression model was raised to 0.3 to ensure that factors which did contribute to the model were not discarded needlessly (32).

Finally, we examined patterns of depressive symptoms and overall patient functioning by comparing the patients who had and who had not recovered at each monthly interval.

## RESULTS

By the 12th month after discharge, 34 (48.6%) of the 70 patients had recovered from their depression. For those who recovered, the average length of time to recovery was 4.9 months after discharge from the hospital. There were no differences in recovery rates based on patients' age, education, marital status, number of children, socioeconomic status, or number of years married (tables 1 and 2). Gender tended toward significance: men were 2.66 times more likely than women to recover within 1 year. Among the seven patients who relapsed, the average time to recovery and relapse was 5.3 and 8.4 months, respectively.

Clinical and psychosocial factors assessed during hospitalization and significantly related to recovery at 12 months included absence of a comorbid illness, shorter hospital stay, later age at onset of depression, lower neuroticism scores, and better-than-average premorbid family functioning. The number of previous hospitalizations was analyzed as a continuous variable and, following the example of Keller et al. (4), as a dichotomy. When hospitalizations were divided into none or one versus two or more, the relationship with recovery was significant (table 1). The chances of recovery were more than 7 times greater if the patient experienced only one or no other hospitalization.

Factors not related to recovery status included current suicide attempts or suicidal ideation, number of previous depressive episodes, serum cortisol level, current dysthymia, severity of depression (Hamilton scale), and family history of psychiatric illness, suicidality, or alcoholism (tables 1 and 2).

Variables included in the original logistic regression were length of hospital stay, age at onset of depression, neuroticism, number of previous hospitalizations (none or one versus two or more), presence versus absence of a comorbid illness, gender, and premorbid family functioning. Gender and premorbid family functioning did not retain their significance and were dropped from the model.

We added the general functioning scales of the Family Assessment Device and the McMaster Clinical Rating Scale to our regression model to see how well family factors contributed to recovery. We did not use forced entry for any variable in the model, nor did we specify the order of entry. The final model estimates are presented in table 3.

In order of significance, the risk factors associated with 1-year outcome of a depressive episode were 1) length of inpatient hospital stay, 2) age at onset of depression, 3) overall level of perceived family functioning, 4) number of previous hospitalizations, and 5) comorbidity. Variables that did not retain significance in the multivariate analyses were neuroticism, premorbid family functioning, gender, and the clinician's rating of overall family functioning. The final adjusted model explained 21% of the variance and correctly identified 78% of the cases.

Other regression models that we tested included removing the seven patients who had relapsed during the follow-up period, omitting the length of stay variable, excluding the family variable, and substituting dysthymia for comorbidity. None of these models fit the data as well as the model presented in table 3.

We separated patients with major depression plus a concurrent illness from those without a concurrent illness to see if the original model would better fit patients whose major depression was not compounded by a comorbid illness. Premorbid family functioning was

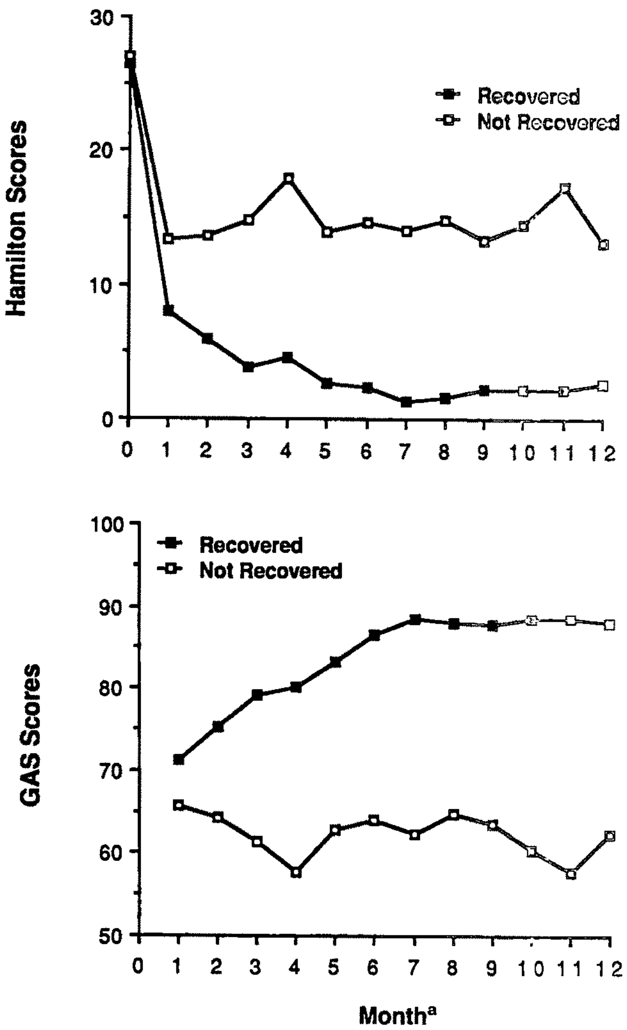
[a] Values were missing for five of the patients; these patients were dropped from this analysis. Model $\chi^2$=28.7, df=5, $L^2$=61.27 (p=0.0001), R=0.456, $R^2$=0.208.

[b] A negative coefficient and multiplier less than 1 indicate a negative relationship with recovery. For example, one more day in the hospital lessened the odds of recovery, an older age at onset increased the chances of recovery.

FIGURE 1. Pattern of Improvement in 70 Depressed Patients Who Did or Did Not Recover by 12 Months After Discharge



[a] For the Hamilton scale, p<0.01 at 1 month and p<0.001 at 2 months (two-tailed t test). For the GAS, p<0.01 at 2 months. For both scales, p<0.001 at months 3–12 (two-tailed t test).

were no differences at the initial assessment between the patients who did and did not recover. The gap in scores between the two groups became significant after only 1 month; thereafter, the recovered patients showed steady improvement throughout the study period.

At the 12-month evaluation an adult family member completed the life events checklist of the Social Readjustment Rating Scale by noting any event that occurred in the previous 6 months. On average, the recovered patients reported significantly fewer events than did those who did not recover (2.9 versus 6.7, t=3.79, df=38.3, p<0.001). Although individual item analysis suggested that positive and negative events occurred to both patients who did and those who did not recover, the percentage of negative events checked was larger for the patients who did not recover than it was for those who recovered (57% versus 33%, $\chi^2$=4.01, df=1, p<0.05).

Patients were asked at the 12-month follow-up about treatment received since their discharge from the hospital. There were no differences between patients who did and did not recover in the percentage who received individual or family therapy. During the follow-up period 22 (71%) of the patients who recovered and 30 (86%) of those who did not received individual therapy ($\chi^2$=2.14, df=1, n.s.); 11 (36%) of the patients who recovered and 15 (43%) of those who did not received family therapy ($\chi^2$=0.37, df=1, n.s.). Not surprisingly, patients who had not recovered by 12 months were more likely to be still receiving pharmacotherapy than those who had recovered (61% [N=22] versus 41% [N=14], $\chi^2$=2.78, df=1, p<0.10).

## DISCUSSION

This exploratory study was designed to focus on factors affecting the course of depressive illness and 12-month outcome. Based on our data, the odds of recovering from a depressive episode within 1 year are 0.94:1, slightly less than a 50-50 chance and similar to other 1-year recovery rates reported in the literature (4–7).

We found that recovery is associated with being male and having a shorter hospital stay, fewer than two previous hospitalizations for depression, older age at onset of depression, lower neuroticism scores, fewer life events reported, no other psychiatric or medical condition, better-than-average premorbid family functioning, less family dysfunction, and better global adjustment after discharge.

Recovery was not associated with marital status, socioeconomic status, severity of the illness at hospitalization, number of previous depressive episodes, suicidality, serum cortisol level, treatment received, or family history of psychiatric illness, alcoholism, or suicidality. Although recovery was associated with comorbidity, we did not find a relationship between a particular type of comorbid illness and recovery status (36).

Multivariate analyses indicated five factors that were the most important in predicting recovery: length of hospital stay, older age at onset of depression, better family functioning, fewer than two previous hospitalizations, and absence of any concurrent illness.

How do these five factors fit into what is known about variables affecting recovery in depression? A shorter hospital stay for patients who were recovered by 1 year would suggest that these patients had a less severe depression; however, there were no differences between patients who did and did not recover in severity of depression at the time of hospitalization as measured by the Modified Hamilton Rating Scale for Depression. Also, length of hospital stay was not significantly correlated with severity of depression.

The family environment of the patient may be salient in that a shorter hospital stay for the recovered patient may be due to a more supportive and better functioning family system. Although family functioning at the acute phase was not related to the length of hospital stay, it was associated with recovery.

We have reported that depressions compounded by other axis I, II, or III disorders significantly prolong the length of hospitalization (36). Although comorbid illness may not increase the severity of depression, a concurrent illness does introduce complicating factors that may lengthen hospital stay and thus affect recovery.

Correlations between length of hospital stay and the other variables in the model were neither substantial nor significant. Further, when length of stay was excluded from the model, the amount of variance explained was reduced to 14% and only 66% were correctly classified. A shorter hospital stay may simply mean that, for some patients, the recovery process starts early in their hospitalization. Alternately, length of hospitalization may reflect other factors not assessed in this study, such as hospital and treating physician philosophies, patient preference, and, increasingly, health coverage.

The association between recovery and older age at onset of depression supports a similar finding by Greenhouse et al. (10); however, our follow-up period was not long enough to determine whether this variable was associated with either recurrence or relapse (15, 17). Patients who were younger at onset of depression (younger than age 30) were more likely to have a psychiatric illness in the family and tended to have poorer family functioning than patients who were older at onset. It may be that patients with an early onset have a higher vulnerability for psychiatric illness and, because of years of stress on the family system, impaired competence in family functioning, both resulting in a more difficult course.

Family functioning factors, seldom included in research on the course of depressive illness, proved to be important in the recovery process. Our finding that poor family functioning at the acute phase was related to poor prognosis is shared by other researchers and has some empirical support (7, 37, 38). A more detailed report on the different dimensions of family function and dysfunction and changes over the course of the depressive episode is forthcoming.

Number of previous depressive episodes did not help to predict course of illness, but the number of previous hospitalizations was predictive of prognosis. However, only when previous hospitalizations were dichotomized to none or one versus two or more did the relationship become significant. Although our figure was lower than that of Keller et al. (12), we were able to replicate the finding of a threshold effect regarding previous hospitalizations. It is unclear whether this finding was a statistical anomaly, but it has some research support and potentially important clinical implications.

Female depressed patients with no concurrent illness were significantly less likely to recover than their male counterparts. Sargeant et al. (39) found an age-gender interaction associated with persistence of depression: older female patients had the most chronic course. The relationship of gender to the course and outcome of major depression is still unclear and is another area that needs further systematic study.

The effect of life events on recovery is also unclear. Some have argued that life events lose their impact in a relatively short period (21, 40). In our study, however, patients who did not recover reported significantly more life events than patients who recovered. It may be that the events included chronic strains or that the patients who did not recover continued to experience new burdens. Although we note the relationship, at this point we are unable to speculate on causal direction.

Finally, a majority of the patients who were recovered at 12 months had, in fact, remitted in less than 6 months after discharge. This suggests that early improvement in the depressive episode may be conducive to long-term improvement or, possibly, to a longer interval of well-being between depressive episodes. It is also possible that there are at least two types of depressive illness with respect to recovery: one that remits quickly and another with a more prolonged course irrespective of treatment given. In the former case, most treatment will be effective, but the latter case represents a challenge to identify which treatment, or combination of treatments, can play a greater role in bringing about a more rapid recovery.

# Anxiety Syndromes as Epiphenomena of Primary Major Depression: Outcome and Familial Psychopathology

William Coryell, M.D., Jean Endicott, Ph.D., and George Winokur, M.D.

*Objective: Anxiety symptoms often appear within depressive episodes, but their significance is uncertain. This study sought to determine whether they indicate the coexistence of a separate disease process and whether they have prognostic significance. Method: A series of patients with primary depression who entered a follow-up and family study included 37 who also had obsessions or compulsions, 93 who had panic attacks, 101 who had phobias, and 196 who had none of these anxiety syndromes. Each of the overlapping groups defined by the presence of a specific anxiety syndrome was compared to the group that had none of these syndromes with respect to baseline demographic, phenomenological, and historical features, illness rates among directly interviewed relatives, and diagnostic stability and clinical outcome at semiannual follow-ups over a period of 5 years. Results: Depressive symptoms at intake were more longstanding and severe among patients with specific anxiety symptoms, and these patients went on to experience more depressive morbidity during the ensuing 5 years. The development of autonomous anxiety disorders was rare, however, and specific anxiety syndromes in the probands did not increase risks for the corresponding disorders among relatives. Conclusions: When restricted to episodes of major depression, anxiety syndromes appear to be prognostically significant epiphenomena rather than indicators of an additional disorder.*

(Am J Psychiatry 1992; 149:100–107)

Anxiety syndromes, specifically those characterized by phobias, panic attacks, obsessions, or compulsions, co-occur with major depression at rates far exceeding those explicable by chance (1). This co-occurrence may reflect causal relationships. Depression may be complicated by obsessions, compulsions, phobias, or panic attacks, or the reverse may be true; i.e., anxiety disorders may give rise to depression. Alternatively, anxiety and depressive syndromes may be expressions of a common diathesis. None of these hypotheses is exclusive of the others; causal relationships may exist in some cases, and other cases may reflect, instead, a common etiology. Indeed, there is empirical evidence for each of these possibilities.

The common diathesis hypothesis can be tested in several ways. First, family study data would offer support if a proband diagnosis of anxiety disorder increased risks for depressive disorder among relatives and, conversely, if a proband diagnosis of depressive disorder raised familial risks for anxiety disorders. In particular, probands with coexisting anxiety and affective syndromes should have relatives with increased risks of both of the corresponding disorders. Most of the relevant family studies have not satisfied these predictions, however. Three studies (2–4) compared probands with panic disorder to normal control probands, and none of them found group differences in risks for affective disorders among relatives. Two studies (5, 6) compared probands with affective disorders to normal control probands; one (6) found an increase in panic disorder among the relatives of affective disorder probands, but the other (5) did not. While most twin studies have not provided the diagnostic detail necessary to investigate this question, Torgersen (7) described 13 monozygotic twin pairs in which one twin had panic disorder. Although four co-twins also had panic disorder, none of them had an affective disorder.

Finally, two studies have described the familial psychopathology of probands with coexisting major depression and panic disorder. One of these (8) found increased rates of anxiety disorders only among the families of probands who had had panic attacks when major depression was absent. Probands who had experienced panic attacks only in the context of depressive episodes had no higher familial rates of anxiety disorder than those of depressed probands who did not have panic attacks. In contrast, Leckman et al. (9) found in-

creased risks for both depression and panic disorder among the relatives of probands with both syndromes regardless of the temporal relationships between these syndromes. The former study (8) may merit more weight, since it determined familial loading entirely from directly interviewed relatives and assessed probands as they presented for the treatment of active symptoms. Leckman et al. (6) only indirectly evaluated a majority of the relatives described. Moreover, they assessed probands during a community survey, and many probands described only past depressive episodes. We suspect that such methods inadequately separate relatives or probands with panic disorder from those with affective disorders.

Studies of diagnostic stability also apply, and these have consistently failed to support the common diathesis concept. Depressed patients who lacked a history of independent anxiety disorders very rarely developed such disorders during follow-up (10, 11). However, neither of these two studies identified subgroups with prominent anxiety symptoms when follow-up began. Diagnostic stability in these particular patients would more directly address the common diathesis hypothesis.

Thus, family study and diagnostic stability data tentatively favor the view that these syndromes coexist because they are causally related. Virtually all well-studied psychiatric illnesses increase risks for major depression (12), and there is no reason to suspect that the anxiety disorders are exceptions to this rule. The reverse may occur as well, and, in fact, a small literature shows that various anxiety syndromes do complicate affective disorders. Coryell et al. (8) and VanValkenburg et al. (13) characterized patients who experienced panic attacks only within depressive episodes, Schapira et al. (14) described phobias precipitated by depression, and several other reports (15–20) concerned obsessions and compulsions temporally confined to depressive episodes. Only the studies of depression with panic attacks (8, 13) described the prognostic significance of these phenomena. Both found that panic attacks were associated with relatively poor outcomes. Whether other anxiety syndromes have similar prognostic significance remains an open question.

To address the issues we have described, the following analyses focus on depressed patients who, at the beginning of follow-up, reported anxiety syndromes temporally confined to depressive episodes. We first consider support for the common diathesis hypothesis. Do these patients often develop autonomous anxiety disorders during follow-up that correspond to the anxiety symptoms present at intake? Are the relatives of these patients at increased risk for the corresponding anxiety disorders or for anxiety disorders in general? Next, we consider the practical implications of anxiety syndromes limited to depressive episodes. Do these coexisting syndromes adversely affect prognosis? If so, are the different anxiety syndromes prognostically equivalent? Finally, are certain outcomes such as suicidal behavior, manic episodes, and substance abuse more or less likely among these patients?

## METHOD

Earlier reports have detailed the family study (21) and 5-year follow-up (12) components of the National Institute of Mental Health Collaborative Program on the Psychobiology of Depression—Clinical Studies. Patients with major depression, mania, or schizoaffective disorder were invited to participate shortly after hospital admission or within 2 months of their first outpatient visit. All subjects were 17 years of age or older, Caucasian, English-speaking, knowledgeable about both biological parents, and free of any brain syndrome, terminal illness, or mental deficiency (IQ <70). Individuals entered the study at one of five sites: Massachusetts General Hospital and Harvard University in Boston, Rush-Presbyterian-St. Luke's Medical Center in Chicago, University of Iowa College of Medicine in Iowa City, New York State Psychiatric Institute and Columbia University in New York, and Washington University School of Medicine in St. Louis.

Trained research assistants reviewed medical records for each proband, administered the Schedule for Affective Disorders and Schizophrenia (SADS) (22), and used the resulting information to generate Research Diagnostic Criteria (RDC) diagnoses (23). They then used the Longitudinal Interval Follow-Up Evaluation (24) to conduct semiannual follow-up assessments.

The Longitudinal Interval Follow-Up Evaluation provided weekly ratings of psychopathology for each of the RDC affective and nonaffective disorders. "Recovery" required 8 contiguous weeks with no more than one or two symptoms at no more than a mild degree. "Relapse" presupposed "recovery" and required the definite reappearance of the corresponding syndrome. This instrument also quantified psychosocial adjustment in diverse areas and tracked relevant events such as hospitalization, outpatient contact, and suicide attempts.

Raters systematically described all treatment directed at psychopathology. These data were first condensed into drug equivalences determined by reference to the relevant literature (available from the first author on request) and then into composite antidepressant scores (25). "Active somatic antidepressant" therapy in the following analyses implies more than 100 mg/day of imipramine or its tricyclic antidepressant equivalent, more than 30 mg/day of phenelzine or its monamine oxidase inhibitor (MAOI) equivalent, any lithium therapy, or any ECT.

Many of these patients were also invited to participate in a family study in which all first-degree relatives 17 years of age or older who could be located and who were willing were interviewed by raters blind to proband diagnosis. The SADS—Lifetime Version (SADS-L) provided structure to these interviews and, as with the probands, medical records were sought and reviewed. Attempts were then made to reinterview each of these relatives 6 years later. Research assistants repeated the SADS-L to review lifetime diagnoses and carefully documented any psychopathology that had appeared since the first interview.

The present report concerns only patients who entered the study with definite primary depression; thus, those with histories of any of the nonaffective RDC disorders listed in the criteria for secondary depression (23) were excluded. Patients with "primary depression and phobia" had clinically significant phobias (scores of 3–6 on SADS item 267) during their index episodes of depression. Those with "primary depression and panic attacks" had met criteria for definite panic attacks (a score of 3 on SADS item 251) during their index episodes, and those with "primary depression and obsessions or compulsions" had these symptoms at the definite level (scores of 3–6 on SADS item 270). These three groups were not mutually exclusive; for instance, some patients with primary depression and panic attacks also had phobias. The final, comparison group, however, was exclusive; patients with "uncomplicated primary depression" had no panic attacks, phobias, obsessions, or compulsions as just defined.

We derived several subscales to quantify the severity of depressive symptoms at intake. In contrast to such traditional severity measures as the Hamilton Rating Scale for Depression (26), the "criteria depression score" used here reflected only the criteria symptoms for RDC major depression. The score was calculated by adding the ratings for each of the corresponding SADS items. For some criteria symptoms, several SADS items applied, and the highest item rating was used. Since there were eight criteria symptoms plus dysphoria, the maximum score was 54. The "endogenous depression score" encompassed those symptoms which constituted RDC endogenous depression. Two of the corresponding SADS items, middle and terminal insomnia, had binary scoring and were arbitrarily assigned values of 3. The total maximum possible endogenous depression score was therefore 51.

Since the patient groups with coexisting primary depression and anxiety were not exclusive of each other, they were not compared statistically. Instead, each of the cosyndromal groups was compared pairwise with the group of patients who had primary depression and no anxiety syndrome. Analyses used t tests for continuous variables and Fisher's exact tests for categorical variables. All p values reported here reflect two-tailed tests.

We used Kaplan/Maier life-table methods (27) for comparisons of times to recovery and times to relapse. These techniques describe all subjects to the point at which they recovered or left the study, so that the effects of censored data were minimized. Group sizes for life-table analyses reflected all subjects with at least 6 months of follow-up and therefore differed from those that considered only subjects who completed all 5 years of follow-up.

## RESULTS

Of 359 patients who entered the study with primary major depression and who completed 5 years of follow-up, 163 (45.4%) exhibited at least one of the specified anxiety syndromes. While the majority (N=95, 58.3%) reported only one of these syndromes, many reported two: 11 (6.7%) had both obsessions or compulsions and panic attacks, 16 (9.8%) had both obsessions or compulsions and phobias, 46 (28.2%) had both panic attacks and phobias, and five (3.1%) had all three types of anxiety symptoms.

### *Demographics and Clinical Features*

At intake, depressed patients with anxiety syndromes described longer episode durations than did patients with no anxiety syndrome (table 1). A regression analysis undertaken to control for the effects of group overlap revealed that panic attacks were independently associated with longer durations (F=9.98, df=1, 355, p=0.002), whereas phobic symptoms (F=0.68, df=1, 355, p=0.41) and obsessive-compulsive symptoms (F=1.89, df=1, 355, p=0.17) were not.

Depressed patients with anxiety syndromes were also generally younger at intake and when first depressed than were patients without anxiety. Patients with anxiety syndromes did not differ from patients without anxiety on Global Assessment Scale (GAS) (28) scores at intake or on levels of optimum functioning in the previous 5 years (table 1). However, the two scales designed to reflect depressive symptoms specifically revealed significantly greater severity among patients with anxiety syndromes.

Again, regression analyses revealed that panic attacks, but not obsessions and compulsions or phobias, were associated with higher symptom levels after control for coexistence of the other two anxiety syndromes; for the endogenous depression score, F=6.70, df=1, 355, p=0.01; for the criteria depression score, F=5.04, df=1, 355, p=0.03. Similarly, controlled associations between obsessions and compulsions or phobias and either the endogenous depression score or the criteria depression score failed to approach significance (no p value was <0.10).

Depressed patients with panic attacks were significantly less likely than nonanxious depressed patients to have bipolar I depression (table 2). Otherwise, they were as likely as patients without anxiety syndromes to have each of the specific depressive subtypes considered. Patients with obsessions or compulsions recalled significantly poorer adolescent friendship patterns than did depressed patients without anxiety syndromes (table 1).

### *Familial Psychopathology*

The families of probands with depression and anxiety syndromes had the same rates of primary depression as did the families of probands with uncomplicated primary depression (table 3). Both phobic and obsessive-compulsive disorders were more common among family members of probands with panic attacks, although panic disorder was not. None of the other anxiety disorders was overrepresented in the families of depressed probands with specific anxiety symptoms.

Since proband groups differed significantly by age,

| Definite endogenous subtype | 121 | 61.7 | 23 | 62.2 | 69 | 74.2 | 70 | 69.3 |

[a] Significantly different from group with no anxiety syndrome ($\chi^2$=4.1, df=1, p=0.04).
[b] Significantly different from group with no anxiety syndrome ($\chi^2$=7.2, df=1, p=0.007).

we used logistic regression to control for proband age. The results were virtually unchanged and, again, only the relatives of probands with panic attacks differed significantly from the relatives of probands with uncomplicated primary depression. The former were significantly more likely to have obsessive-compulsive disorder ($\chi^2$=4.4, df=1, p=0.04) or phobic disorder ($\chi^2$= 11.9, df=1, p=0.0006). This pattern remained when we compared groups by the proportions with positive family histories.

The most prominent type of phobia (agoraphobia, social phobia, simple phobia, or mixed phobias) was scored for 30 of the 32 individuals who had phobic disorder and who were relatives of depressed probands with panic attacks. Agoraphobia was most prominent in nine individuals (30.0%), social phobia in none, simple phobia in 16 (53.3%), and mixed phobias in five (16.7%). This distribution did not differ significantly from that for the 37 individuals who had phobic disorder and were relatives of probands without anxiety syndromes; the corresponding numbers and proportions were eight (21.6%), three (8.1%), 19 (51.4%), and seven (18.9%), respectively. Thus, the association between panic attacks among probands and phobic disorder among their relatives was not specific to agoraphobia.

### *Diagnostic Stability*

Of the 37 patients who entered this study with primary depression and obsessions or compulsions, 28 recovered. Of these, 14 (50.0%) developed at least one

new episode of major depression, but only two (7.1%) developed separate episodes of obsessive-compulsive disorder. Of the 196 patients with primary depression and no anxiety syndrome, 182 recovered and, of these, 78 (42.9%) developed new episodes of major depression and three (1.6%) developed separate episodes of obsessive-compulsive disorder. The risks for new episodes of obsessive-compulsive disorder in these two groups were not significantly different.

Patients who began the study with panic attacks (N=93) were similarly unlikely to develop autonomous panic disorder. Of the 83 patients who recovered, 44 (53.0%) developed new episodes of major depression, but only five (6.0%) developed autonomous episodes of panic disorder. However, this risk was significantly higher than that seen for patients who entered the study with no anxiety syndrome; none of these patients developed separate episodes of panic disorder (p=0.003, Fisher's exact test).

New episodes of phobic disorder were somewhat more common than were new episodes of panic disorder or obsessive-compulsive disorder. Of the 95 patients who began follow-up with primary major depression and phobias and went on to recover, 46 (48.4%) had new episodes of major depression and 12 (12.6%) had new, discrete episodes of phobic disorder. Five (2.6%) of the 196 patients who began follow-up with no anxiety syndrome developed phobic disorder ($\chi^2$= 10.7, df=1, p=0.005).

### *Course and Outcome*

Depressive symptoms were more persistent and recurrent among patients with coexisting anxiety syn-

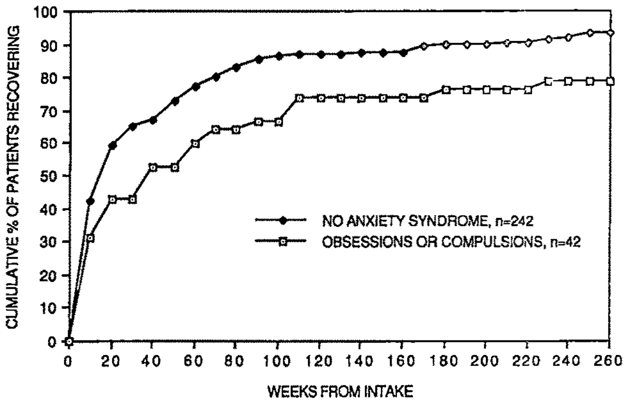
dromes than they were among patients without anxiety syndromes, although many pairwise comparisons did not reach significance (tables 4 and 5). The anxious patients had considerably longer median times to recovery; patients with no anxiety syndromes took a median of 14 weeks to recover, while those with obsessions or compulsions took 39.5 weeks ($\chi^2$=5.3, df=1, p=0.02), those with panic attacks took 20 weeks, and those with phobias took 28 weeks ($\chi^2$=5.0, df=1, p=0.03). Moreover, among those who recovered, anxiety syndromes were associated with shorter times to relapse. The median time to relapse was 80 weeks for those without anxiety syndromes but 37 weeks for those with obsessions or compulsions, 62 weeks for those with panic attacks, and 44 weeks for those with phobias (significantly different from those without anxiety syndromes, p=0.03, Fisher's exact test).

Of the three anxiety syndromes, obsessions and compulsions clearly had the gravest prognostic significance. Figure 1 incorporates all subjects who completed at least 6 months of follow-up and shows that this outcome difference emerged in the first year of follow-up. Time to recovery among these patients was twice that for patients without anxiety syndromes, and this group ranked lowest on all of the six measures of persistence or recurrence of depressive symptoms. Similarly, both the GAS scores and the raters' global assessments of psychosocial functioning ranked patients with obsessions or compulsions as last, or most impaired, at 6 months, 2 years, and 5 years of follow-up.

**FIGURE 1. Recovery From Index Episode of Primary Major Depression of Patients With No Anxiety Syndrome and Patients Who Also Had Obsessions or Compulsions**[a]



[a]Significant difference between groups ($\chi^2$=5.3, df=1, p=0.02).

Regression analyses were conducted for the outcome measures that most robustly distinguished patients with anxiety syndromes from those without anxiety syndromes: likelihood of recovery from the index episode, number of weeks depressed during follow-up, GAS score at 2 years, and GAS score at 5 years. After control for coexistence of panic attacks and phobias, the presence of obsessive or compulsive symptoms strongly predicted a lower rate of recovery ($\chi^2$=11.8, df=1, p=0.0006) and a greater number of weeks depressed during follow-up ($\chi^2$=13.8, df=1, p=0.0002). The presence of phobias predicted a low rate of recovery at a nearly significant level ($\chi^2$=3.2, df=1, p=0.07) after control for the coexistence of the other two anxiety syndromes. The presence of obsessions or compulsions also predicted lower GAS scores at 2 years (F=16.6, df=1, 355, p=0.0001) and, at a borderline significance level, at 5 years (F=3.6, df=1, 355, p=0.06). The relation between phobic symptoms at intake and GAS score at 5 years also approached significance (F=3.2, df=1, 355, p=0.07). None of the other anxiety syndrome/outcome relationships approached significance after control for other coexisting anxiety syndromes. To recapitulate, the presence of obsessions or compulsions predicted, at highly significant levels, a lower rate of recovery, more weeks depressed during follow-up, and a lower GAS score at 2 years, even after statistical control for other anxiety syndromes. The relations between phobic symptoms and outcome approached significance for the likelihood of recovery and for the GAS score at 5 years.

We next considered the possibility that patients with anxiety symptoms had poorer outcomes because they were at least somewhat more likely to manifest separate anxiety disorders. To explore this, we repeated the comparisons displayed in table 4 after excluding the patients who developed autonomous anxiety disorders during follow-up. The results were essentially unchanged. One difference (patients with obsessions or compulsions were significantly more likely to be hospitalized during follow-up) became nonsignificant when diagnostically unstable patients were excluded. However, two other insignificant differences became significant; patients with panic attacks now had a significantly shorter median time to relapse (56.0 weeks; $\chi^2=3.9$, df=1, p=0.05) and significantly lower (worse) GAS scores at 6 months (mean±SD=58.0±13.8; t=–2.2, df=208.9, p=0.03).

Approximately three of every four patients received active antidepressant therapy at some time during follow-up, and the aggregate duration of such therapy was slightly more than 1 year (tables 4 and 5). None of the anxiety syndromes was associated with a higher likelihood of antidepressant therapy. Patients with these complications were no more or less likely than patients without them to receive such therapy, nor were any anxiety syndromes associated with treatment sustained for greater or lesser periods.

## DISCUSSION

The direct and repeated interviews of relatives undertaken in this study revealed little evidence that anxiety syndromes confined to episodes of primary depression implied separate disease processes. Probands with depression and coexisting anxiety syndromes had relatives with no less risk for primary depression than relatives of probands with uncomplicated primary depression, and the complicating anxiety syndromes were not reflected in increased risks for the corresponding disorders among relatives. Probands with panic attacks had increased familial loadings for obsessive-compulsive disorder and phobic disorder, but this pattern has not been noted previously and was thus unexpected. Specifically, Noyes et al. (4) found no increase in phobic disorder among the relatives of panic disorder probands. Therefore, our finding must be replicated before it is given weight in generating or supporting hypotheses. On balance, the lack of specificity between proband anxiety syndromes and familial anxiety disorders argues against the common diathesis hypothesis described previously.

These analyses leave unclear the prognostic primacy of any of these syndromes over the others. Obsessions and compulsions were clearly the most important predictors of morbidity when the course of illness was tracked prospectively. However, a retrospective view at intake revealed panic attacks as the more important correlate of severity and chronicity. Also, phobias independently predicted several outcome measures at levels approaching statistical significance. These data, while they indicate a prognostically complex interrelationship among these syndromes, permit the tentative conclusion that panic attacks and obsessions or compulsions are the more important of the three.

Depressed patients with associated obsessions or compulsions, panic attacks, or phobias were unlikely to develop these symptoms as autonomous disorders during follow-up. They were much more likely to develop, instead, further episodes of primary depression. These findings accord with earlier studies that showed high diagnostic stability for primary depression (10, 11), although the test of stability applied in the present study was more rigorous, since these subjects were particularly prone to diagnostic instability. The small but significant level of diagnostic change that did occur may indicate imperfections in the temporal sequencing of syndromes; that is, some patients may have failed to recall previous, autonomously occurring anxiety disorders. On the other hand, some individuals may suffer from two illnesses; data from this study, though, suggest that such coincidences are very infrequent.

Although the anxiety syndromes identified predicted very little diagnostic instability, they nevertheless had prognostic importance. The depressed patients with any one of these anxiety syndromes had poorer outcomes than did the depressed patients without an anxiety syndrome. If these symptoms simply implied the presence of the corresponding anxiety disorder, a poorer outcome in these patients would be entirely unsurprising. However, follow-up showed that very few patients actually had autonomous anxiety disorders, and the prognostic disadvantage conveyed by these anxiety symptoms was undiminished after the exclusion of diagnostically unstable patients from the analysis. These symptoms, then, appear to be epiphenomena which, like delusions (29), signify a more severe and persistent illness.

# A Double-Blind Comparison of Valproate and Lithium in the Treatment of Acute Mania

Thomas W. Freeman, M.D., Jeffrey L. Clothier, M.D., Peggy Pazzaglia, M.D.,
Michael D. Lesem, M.D., and Alan C. Swann, M.D.

*Objective: This study was carried out to compare the efficacy of lithium carbonate with that of valproate in acute mania and to determine whether pretreatment clinical characteristics, such as the presence of a mixed affective state, might predict a differential response to the two drugs. Method: Twenty-seven patients meeting* DSM-III-R *criteria for acute manic episodes underwent a 3-week, randomized, double-blind, parallel-groups trial of treatment with lithium carbonate or valproate. Symptom severity was measured by using the Schedule for Affective Disorders and Schizophrenia, change version (SADS-C), the Global Assessment Scale (GAS), and the Brief Psychiatric Rating Scale (BPRS). Drug effects were compared by using repeated measures analysis of variance (ANOVA). Results: At the end of the study, nine of 14 patients treated with valproate and 12 of 13 patients treated with lithium had responded favorably, as measured by changes in the SADS-C mania, BPRS, and GAS scores. Elevated pretreatment SADS-C depression scores were associated with good response to valproate. ANOVA revealed a significant interaction between drug and mixed affective state with respect to treatment response. Conclusions: Lithium and valproate were both effective in improving manic symptoms, and lithium was slightly more efficacious overall. Unlike the case with lithium, favorable response to valproate was associated with high pretreatment depression scores. Therefore, treatment with valproate alone may be particularly effective in manic patients with mixed affective states.*

(Am J Psychiatry 1992; 149:108–111)

Lithium salts are the standard treatment for acute episodes of mania. Despite the efficacy and relative lack of ill effects of lithium, a substantial number of patients with manic disorder do not respond to treatment with lithium alone. The best-defined groups of patients who do not respond well to lithium are those with mixed affective states (1–3) and with four or more cycles per year (4). Of these groups, patients with mixed presentations are the more common, representing 30%–50% of manic episodes (1). However, prospective treatment trials provide essentially no information about effective regimens for the mixed state.

Emrich et al. (5, 6) and Post et al. (7) suggested that certain drugs previously used as anticonvulsants, including carbamazepine and valproate, may be effective in manic episodes. These drugs would be especially useful if they were effective in patients who would not be expected to respond well to lithium. Data from retrospective studies suggest that valproate may be effective in patients with rapid cycling (8) and that open treatment with valproate was effective in mixed states (9). As a preliminary investigation of differential predictors of response to lithium compared with valproate, we have carried out a double-blind, parallel-groups trial of lithium versus valproate in patients admitted to our clinical research unit with acute manic episodes.

## METHOD

Twenty-seven patients, 21 women and six men, were admitted to our clinical research unit. The patients were consecutive admissions meeting *DSM-III-R* criteria for a manic episode. After giving informed consent, patients entered a 4–7-day placebo washout period during which the *DSM-III-R* diagnosis of manic episode was

confirmed independently by two board-certified psychiatrists (J.L.C., M.D.L., or A.C.S.) using a semistructured interview and a *DSM-III-R* checklist. Baseline clinical ratings and medical and laboratory evaluations, including physical and neurological examinations, CBC, liver and thyroid function tests, electrolytes, EEG, and ECG (if the patient was over 50 years old), were completed during this period. Patients with abnormal EEG, liver function, thyroid function, or hematologic findings were excluded from the study, as were patients with positive urine drug screens and patients with focal neurological abnormalities. Patients were also excluded if they had *DSM-III-R* diagnoses of drug or alcohol dependence or drug or alcohol abuse within 12 months before admission or before the onset of major affective episodes. Eight subjects assigned to valproate and seven subjects assigned to lithium had histories of drug or alcohol abuse at some point during the course of their bipolar disorder.

Other clinical characteristics of the two groups were also comparable. Time since the first episode averaged 12.3±6.2 years (range=0–22) for valproate patients and 8.8±5.9 years (range=0–20) for lithium patients; each group included one patient having a first manic episode. Twelve patients in the valproate group had been treated with lithium; seven had failed to respond at least once. In the lithium group, 10 patients had previously been treated with lithium, and six had at least one treatment failure. No patients had ever received valproate.

Patients were assigned randomly to treatment with lithium or valproate in a double-blind fashion. The lithium group, consisting of 10 women and three men, received lithium citrate as the elixir, starting at 0.5 meq/kg per day. The dose of lithium was increased until either a maximum dose of 1800 mg/day, level of 1.5 mmol/liter, dose-limiting side effects, or clinical improvement occurred. Lithium levels at the end of the study ranged from 0.8 to 1.4 mmol/liter. The valproate group, consisting of 11 women and three men, was started on a fixed-dose regimen of valproate as the elixir. Valproate patients received 1500 mg/day during the first week, 2250 mg/day during the second week, and 3000 mg/day during the third week, unless their symptoms had remitted or they experienced dose-limiting side effects. Valproate levels were 85±17 μg/ml (range=67–118) at the end of the first week, 98±27 μg/ml (range=71–147) at the end of the second week, and 98±17 μg/ml (range=65–126) at the end of the third week. Medicine was given three times a day, diluted by the research pharmacist to a total volume of 30 ml with flavored diluent.

Plasma drug levels were monitored on days 5–7 of each week, the results were sent to the research pharmacist, and the dose was adjusted by a nonblinded, nontreating physician. The Schedule for Affective Disorders and Schizophrenia, change version (SADS-C) (10), the Global Assessment Scale (GAS) (11), and the Brief Psychiatric Rating Scale (BPRS) (12) were administered at the time of dose adjustments.

Rescue medication, including chloral hydrate and lorazepam, was allowed for extreme behavioral problems not responding to nonpharmacological interventions. The amount of rescue medication needed did not differ between the treatment groups: the patients assigned to valproate received 2.9±5.9 g of chloral hydrate and 5.7±5.9 mg of lorazepam and the patients assigned to lithium received 4.4±5.4 g of chloral hydrate and 5.0±5.6 mg of lorazepam. Four patients in each group required no rescue medication.

Five patients out of the 27 whose outcomes were evaluated did not complete the full 21-day protocol but dropped out after 8–20 days of treatment. These included two patients assigned to valproate (one responder and one nonresponder) and three patients assigned to lithium (two responders and one nonresponder). Patients dropped out because of deterioration, recovery, or desire to leave the study. No patients had to leave the study because of adverse drug effects.

Statistical comparisons used Student's two-tailed t test or analysis of variance (ANOVA), as described in the Results section. Categorical response and nonresponse were defined essentially as described by Secunda et al. (1). An improvement in the SADS-C mania factor of at least 50% was defined as a favorable outcome. Patients whose pretreatment SADS-C depression scores were greater than 30 were defined as having mixed mania. There were four patients with mixed mania in each drug treatment group.

## RESULTS

Comparison of the lithium and valproate treatment groups revealed no significant differences in initial BPRS, GAS, or SADS-C factor scores (Student's t test). There were also no differences between the groups in age or sex.

Nine of the valproate patients and 12 of the lithium patients had favorable outcomes after 3 weeks of treatment. In neither group did responders differ from nonresponders with respect to drug doses or plasma drug levels or in pretreatment SADS-C mania scores.

Table 1 shows initial and final SADS-C mania scores for all patients treated with lithium and with valproate and for responders to the two drugs. Pretreatment mania scores were nonsignificantly higher in patients assigned to valproate. Neither pretreatment scores nor scores after treatment differed significantly between lithium- and valproate-treated patients. Repeated measures ANOVA, however, showed a significant drug group effect, and posttreatment mania scores were higher in patients given valproate.

Table 1 also summarizes the effects of lithium and valproate on BPRS scores and on global impairment as measured by the GAS. As with the SADS-C mania factor, the effects of treatment appeared highly significant. In addition, there was a trend toward a significant group effect for BPRS scores. Table 1 also shows the SADS-C depression scores in responders and nonresponders to valproate before and after treatment. Pre-

**TABLE 1. SADS-C Mania, BPRS, GAS, and SADS-C Depression Scores of Patients With Acute Mania Before and After Treatment With Valproate or Lithium**

| | Score | | | |
|---|---|---|---|---|
| | Before Treatment | | After Treatment | |
| Test and Group | Mean | SD | Mean | SD |
| SADS-C mania[a] | | | | |
| All patients given valproate (N=14) | 52.9 | 12.3 | 27.1[b] | 20.9 |
| Patients who responded to valproate (N=9) | 54.2 | 9.8 | 12.9 | 9.2 |
| All patients given lithium (N=13) | 43.4 | 20.3 | 10.2[b] | 8.8 |
| Patients who responded to lithium (N=12) | 44.7 | 20.6 | 9.0 | 8.2 |
| BPRS total[c] | | | | |
| All patients given valproate (N=14) | 28.4 | 9.4 | 10.6 | 9.1 |
| All patients given lithium (N=13) | 24.1 | 9.8 | 4.3 | 5.7 |
| GAS[d] | | | | |
| All patients given valproate (N=14) | 30.9 | 14.9 | 61.9 | 20.8 |
| All patients given lithium (N=13) | 27.6 | 12.6 | 71.2 | 14.6 |
| SADS-C depression | | | | |
| All patients given valproate (N=14) | 18.9 | 15.9 | 9.1 | 8.4 |
| Patients who responded to valproate (N=9) | 25.6[e] | 15.8 | 9.0 | 8.9 |
| Patients who did not respond to valproate (N=5) | 7.0[e] | 6.3 | 9.4 | 7.5 |
| All patients given lithium (N=13) | 23.6 | 9.5 | 5.7 | 8.1 |

[a] Repeated measures ANOVA: group effect, F=7.13, df=1, 25, p=0.013; response effect, F=45.8, df=1, 15, $p<10^{-4}$; interaction, F=0.75, df=1, 25, n.s.

[b] Significant difference in posttreatment score between all patients given valproate and all patients given lithium (t=2.12, df=25, $p<0.05$).

[c] Repeated measures ANOVA: group effect, F=3.2, df=1, 25, p=0.08; response effect, F=76.9, df=1, 25, $p<10^{-4}$; interaction, F=0.4, df=1, 25, n.s.

[d] Repeated measures ANOVA: group effect, F=0.73, df=1, 25, n.s.; response effect, F=85, df=1, 25, $p<10^{-5}$; interaction, F=2.9, df=1, 25, n.s.

[e] Significant difference between responders and nonresponders to valproate (t=2.3, df=12, $p<0.05$).

treatment depression scores were significantly higher in valproate responders than in nonresponders.

Examination of response in patients with mixed versus nonmixed mania revealed that all four patients with mixed mania receiving valproate responded, but five of 10 patients with nonmixed mania responded. Unlike the case with valproate, a mixed state was associated with relatively unfavorable response to lithium: the one lithium nonresponder had a mixed presentation, and posttreatment mania scores were significantly higher in the four patients with mixed mania (18.0±4.5) than in the nine patients with nonmixed mania (6.7±8.0) treated with lithium (t=2.3, df=11, $p<0.05$). ANOVA revealed a significant interaction between mixed presentation and drug treatment outcome (F=4.2, df=1, 25, $p<0.05$), lending further support to the possibility that lithium and valproate differ in their effects on patients with mixed and nonmixed mania.

## DISCUSSION

Only a small number of patients have been studied in controlled treatment trials with valproate (8). The 64% response to valproate found in the current study was similar to the findings of previous reports. Pope et al. (13) recently reported a 53% response rate to valproate in a placebo-controlled study, but their patients were selected for previous nonresponse to or intolerance of lithium. The response to lithium in our patients was somewhat higher than generally reported. Overall, lithium appeared to be slightly more efficacious than valproate. The difference was clearest among patients with nonmixed mania: all nine of the patients with nonmixed mania given lithium responded to it, but five of 10 patients with nonmixed mania given valproate responded to that drug. In contrast to the case with lithium (1), a mixed state appeared to be associated with better response to valproate: responders had higher pretreatment depression scores than did nonresponders (table 1), and the rate of response was higher in patients with mixed mania than in patients with nonmixed mania. These data, although preliminary, suggest that valproate and lithium may be effective in different groups of manic patients.

Table 1 shows that depressed mood, as well as mania, improved in patients treated with valproate. We previously reported that lithium improved depression in patients with mixed mania (14). Unlike valproate, however, lithium did not improve manic symptoms in these patients.

Valproate has a number of characteristics that make it an attractive alternative treatment for patients with bipolar disorder. The drug is generally well tolerated, does not induce hepatic metabolism of itself or of other drugs, and has relatively few interactions with psychotropic drugs (15). These features may make valproate a useful adjunct in the treatment of complicated patients who do not respond to single agents and a possible alternative treatment for patients who generally respond less well to lithium, such as patients with mixed mania. There are some disadvantages to its use, however. Valproate is teratogenic and should be used with caution in fertile women (16). Valproate can cause mild to moderate elevations in hepatic enzymes and has been linked to severe liver damage, especially in children (17). Other side effects that may be troublesome include weight gain and alopecia.

Although the results of this study suggest that patients with mixed mania may respond relatively well to valproate, they should be interpreted with caution. The sample was not large, women were overrepresented, the response rate to lithium was unusually high, and the patients assigned to valproate appeared to be more severely ill. It will be valuable to undertake larger studies investigating pretreatment clinical factors associated with nonresponse to lithium and response to alternative treatments.

# *DSM-IV* and New Diagnostic Categories: Holding the Line on Proliferation

Harold Alan Pincus, M.D., Allen Frances, M.D., Wendy Wakefield Davis, M.Ed., Michael B. First, M.D., and Thomas A. Widiger, Ph.D.

*The authors discuss aspects of the decision-making process for including "new" diagnostic categories in* DSM-IV. *They detail the different kinds of new categories proposed for inclusion in* DSM-IV *and discuss the risks and benefits of incorporating them. The authors comment on whether new diagnostic categories should be included in official nosologies as a stimulus for research or as a culmination of research. They also highlight problems with "sunsetting" diagnoses. The criteria for change in* DSM-IV*—a way to deal with the expanding array of proposals for additional diagnostic entities—are discussed. The authors also offer a series of specific examples of the different kinds of new categories being considered for inclusion in* DSM-IV.

(Am J Psychiatry 1992; 149:112–117)

There has been a tendency for official nomenclatures to recognize more and more diagnostic categories. In 1840 the U.S. census included only one category for mental disorders. The 1880 census was expanded to include seven different categories of mental disorders. In 1917 the Committee on Statistics of the American Psychiatric Association developed a classification system incorporating 59 disorders (1). By the time of *DSM-I,* in 1952, the diagnostic system had grown to 106 categories. In 1968 *DSM-II* included a total of 182 diagnostic categories. The biggest spurt came with *DSM-III,* in which the number of categories reached 265, and in *DSM-III-R* the increase continued to 292 categories.

The pressure to add new categories or to split existing ones has continued unabated. In the last 2 years of our work on *DSM-IV,* we have received 94 suggestions for new diagnostic categories. Some of these suggestions represent considerable thought and effort by distinguished researchers and clinicians in the field. Others have been offered more as tentative ideas requiring further elaboration. The suggestions also vary in the degree to which they draw on historical tradition and/or have a significant empirical foundation.

The major rationale for most new diagnoses suggested for *DSM-IV* is the perceived need to increase the coverage of the system. The proposed new diagnosis is intended to describe a pattern of symptoms not captured in the existing categories. In some cases the new category represents a construct that is not already included in *DSM-III-R* (e.g., acute stress disorder, dementia with mixed Alzheimer's and vascular features). In other instances the proposed category represents a specific subtype of an existing disorder with purported treatment implications or other clinical implications (e.g., atypical depression, postpartum depression). In still other cases the suggested new category is similar to currently existing categories but subthreshold in its requirements (e.g., "minor depression" to fill the niche for describing depression of a severity that is associated with impairment but which does not meet the criteria for major depression or the duration criteria for dysthymia and which is not associated with a particular stressor as in adjustment disorder).

There are two ways to make new diagnostic distinctions in *DSM-IV:* inclusion of either new diagnostic categories or new subtypes or modifiers. Proposals for new categories have included establishing specified codes and rubrics or labels as well as full sets of criteria. Two examples, acute stress disorder and mixed anxiety and depression, are discussed in detail later. Proposals for adding a subtype to, or providing a "modifier" or a specification for, an already existing disorder generally, although not always, do not include establishing a separate code. There have been suggestions for subtyping bulimia nervosa, specifying that atypical or reverse vegetative features are present in several types of mood disorders, and indicating the presence of self-injurious behavior that accompanies certain disorders.

In this article we discuss the implications of incorporating additional diagnoses in *DSM-IV.* We begin with an evaluation of the benefits and risks in determining the appropriate coverage of *DSM-IV.* Next, we discuss whether new diagnoses should be added to *DSM-IV* as a way of stimulating research or whether they should be included in the official nomenclature only as the culmination of already existing and convincing research. We also discuss why it is more difficult to eliminate old categories than to incorporate new ones. Given these considerations, we explain the criteria we are applying in the development of *DSM-IV* to help us make decisions about proposed diagnostic categories. Finally, to illustrate issues raised in this article, we examine three diagnostic categories that have been proposed for inclusion in *DSM-IV.*

## RISKS AND BENEFITS OF INCORPORATING ADDITIONAL DIAGNOSTIC CATEGORIES

Those who identify the need for a new diagnostic category are often concerned that the lack of a specific category with criteria, rubric, and codes will result in a condition being ignored by practitioners, researchers, and educational programs. Placement in the "not otherwise specified" diagnostic categories, which are provided for residual conditions and other conditions not explicitly discussed elsewhere and which now include many categories being proposed for *DSM-IV,* is often considered inadequate. At the same time, there is almost always a considerable price to pay for the increased coverage provided by any new category. The benefit of more precise diagnoses for some individuals must be balanced against the risk of making incorrect diagnoses for other individuals (i.e., false positives) once the diagnosis is in widespread use beyond the setting in which it originated.

New diagnoses are usually offered by specialists who have great expertise in a specific area and whose experience is based on highly selected referral patterns to their clinical or research practice. Sets of criteria developed in specialty programs, however, will be used, as all of *DSM-IV* will be used, in widely diverse populations and by much less expert assessors. For example, a new set of criteria for bipolar II disorder would probably identify few false positives if applied by mood disorder experts in a mood disorders clinic. The same set of criteria applied more generally might result in a high number of individuals given inaccurate diagnoses, with significant treatment implications. It is often difficult to discriminate hypomania from brief periods of euthymia in patients with longstanding depressive episodes. This becomes particularly problematic in this diagnostic category, which hinges on the presence of a history of hypomanic episodes.

There are other serious potential costs that accompany increased coverage. The additional explanatory value provided by each new diagnosis must be balanced against the added weight it places on an already quite cumbersome system of classification. New diagnoses that are offered to cover very rare and exotic conditions may add unnecessary complexity to the system for a very low yield in improved coverage. Additional categories cut the diagnostic pie into smaller and smaller pieces, which may create definitional overlap across categories and increase, perhaps inappropriately, levels of comorbidity among near-neighbor categories. When we recognize new disorders that frequently co-occur with other new or existing disorders, we may be reifying as separate entities components of a single complex syndrome.

Some of the proposed diagnostic categories would increase the coverage of the *DSM* system to include conditions which are below the current thresholds set for severity or duration (e.g., minor depression). The thresholds established in *DSM,* however, may not always separate sufferers (those who have impairment or distress) from nonsufferers; that is, "subthreshold" is not the same as "subclinical." Because many individuals struggle with these below-threshold conditions, clinicians and researchers hope to incorporate descriptions of these disorders in the diagnostic nomenclature so as to increase their identification and treatment. Many of these disorders may be more prevalent in the general population; thus, incorporating these categories in the nomenclature would dramatically increase the apparent overall prevalence of mental disorders.

Furthermore, some new and unproven diagnoses may lead to a trivialization of the construct of mental disorders and/or its misuse. All of these concerns are especially troubling if there is a lack of solid evidence that the new diagnoses are useful in predicting prognosis, treatment selection, or outcome.

## ARE NEW DIAGNOSES MEANT TO STIMULATE RESEARCH OR RESULT FROM IT?

An argument that is often advanced for a new diagnosis, particularly one which is supported by very limited evidence, is that its inclusion in *DSM-IV* is necessary to stimulate research in an area which has received insufficient attention. There are several mechanisms through which such stimulation is anticipated. The description of a new diagnosis and provision of a set of criteria make it more likely that this diagnostic area will capture the attention of clinical researchers and assist in the development of instruments which reflect a consensus on ways of making the diagnosis across research programs. There is also the unfortunate presumption that inclusion in *DSM* will increase the credibility of the area for various research funding agencies, pharmaceutical companies, and regulatory agencies. It is often pointed out that *DSM-III* and *DSM-III-R* have been major facilitators of research efforts in a number of areas that might have remained much more obscure and unresearched if they had not been included in the official nomenclature. There are some who maintain that one of the most important goals of *DSM-IV* should be this identification of important new diagnostic questions as a guide to future research efforts.

Balancing these arguments is a concern that including an unproven experimental diagnostic category in *DSM-IV* may confer upon that category an approval which it does not yet merit, with possible negative consequences for clinical practice, research, and educational efforts. Such categories should not be included solely to increase research efforts. Instead, we encourage clinicians and researchers to use the more traditional approach of publishing in peer-reviewed journals as a means of increasing interest in and communication about certain proposed diagnostic categories. It is our sense that research should drive *DSM* and not the other way around. It is much more appropriate to incorporate diagnoses once the need for their inclusion has been well documented in the published literature. Given the current state of research efforts, it no longer makes sense to consider including a diagnostic category in the absence of empirical support, even if a group of clinicians agree that the category might be a useful one. It is impossible to predict in the absence of research how a diagnosis and its criteria will perform.

We have, however, made plans for the development of a *DSM-IV Sourcebook*, which will be published in conjunction with *DSM-IV*. The *DSM-IV Sourcebook* will include summaries of all of the published and unpublished data the work groups have considered in their work on *DSM-IV*. A summary of the data available on each proposed new diagnostic category will be included. The *Sourcebook* will provide a comprehensive compendium of recommendations for needed future research. We are also considering incorporating an appendix in *DSM-IV*, similar in some ways to the appendix included in *DSM-III-R*, for proposed diagnostic categories that are not ultimately included in the body of *DSM-IV*. Such an appendix would include only the proposed diagnostic categories for which a careful literature review has been completed.

## PROBLEMS IN "SUNSETTING" DIAGNOSES

In reaction to the remarkable expansion of new diagnostic categories introduced by *DSM-III* and *DSM-III-R*, the question has been raised whether the same high standards of empirical support required for new diagnoses should also be applied to existing categories. There are clearly categories in *DSM-III-R* which are based on such limited evidence that they would not meet current standards for inclusion. Nonetheless, there are a variety of reasons to demand more support for new than for existing categories. A conservative approach to *DSM-IV*—one that hopes to minimize arbitrary changes based purely on expert consensus—must oppose the removal of existing categories as well as the addition of newly proposed categories in the absence of strong evidence recommending either action. The burden of proof generally rests on providing convincing data for either the removal or the addition of categories in preference to keeping the status quo.

Even with this caveat, there are several diagnoses in *DSM-III-R* for which a review of the evidence may indeed lead to a recommendation that they not be included in *DSM-IV*. For example, several diagnoses in the section on child and adolescent disorders, including identity disorder, overanxious disorder, and avoidant disorder, were included in *DSM-III* with little empirical support and may be better accounted for by other diagnoses in the system. *DSM-III-R* also has several categories of gender dysphoria that may be better organized into one category.

## TOWARD BALANCED SOLUTIONS

*DSM-III* and *DSM-III-R* were inclusive in their attitude toward new diagnoses. Spitzer et al. (2) stated that "one of the guiding principles in the development of *DSM-III* has been an attempt to include in the classification all conditions that a significantly large group of clinicians believe are of clinical importance, providing that the condition can be reliably defined so that it can be distinguished from other conditions." Spitzer et al. (3) further explained that "because the *DSM-III* classification is intended for the entire profession, and because our current knowledge about mental disorder is so limited, the Task Force has chosen to be inclusive rather than exclusive . . . . If there is a general agreement among clinicians, who would be expected to encounter the condition, that there are a significant number of patients who have it and that its identification is important in their clinical work, it is included in the classification." More recently, Kass et al. (4) noted that "it is often necessary to recommend for general use a diagnosis for which only face validity can be demonstrated." The approach used in *DSM-III* and *DSM-III-R* for the consideration of new diagnostic categories was appropriate given the amount of empirical information available at the time in which they were developed. We are fortunate that in the development of *DSM-IV* we are able to draw on a significantly larger pool of information made possible by the publication of *DSM-III* and *DSM-III-R*.

As we have considered the criteria for including diagnostic categories in *DSM-IV,* we have taken into account expressions of concern about the ways in which new diagnoses were incorporated in *DSM-III* and *DSM-III-R.* For example, what constitutes "general agreement" among clinicians has never been particularly clear. Furthermore, the lack of specific information and documentation about the decision-making process and rationale in *DSM-III* or *DSM-III-R* may have given some people the impression that the decisions which were ultimately made were politically rather than empirically driven.

In preparing *DSM-IV,* we will attempt to strike a balance between differing attitudes toward the inclusion of new diagnoses. There are many who will be disappointed when one or another proposed category is not included and who warn us that failing to include this or that particular diagnosis will result in a deficient system which will cripple clinical practice and research efforts. We are also advised, however, that to continue the rush of new diagnoses will undercut the empirical foundations and credibility of the system.

This more conservative viewpoint toward new diagnoses has been most clearly and succinctly articulated by Blashfield et al. (5), who have delineated a series of specific and stringent criteria for the inclusion of new categories. We are in substantial agreement with the spirit of their position but perhaps would be more flexible in applying it. From the outset of the development of *DSM-IV,* we have maintained an ongoing discussion about the criteria that could be applied to making decisions about adding and subtracting categories. In an early *DSM-IV* methods conference, criteria for adding and subtracting diagnoses (E. Frank, presentation at 1988 conference) were discussed in detail. Participants agreed that it was important to have information on how a proposed diagnostic category would facilitate communication, on the category's clinical utility, reliability, and descriptive validity, and on associated external validators. The external validators (K. Kendler, presentation at 1988 conference) to be examined would include antecedent validators (e.g., demographic characteristics, premorbid personality, family history, and precipitating factor), concurrent validators (e.g., biological, physiological, and psychological variables), and predictive validators (e.g., diagnostic consistency, social, occupational, and other follow-up variables, and treatment response). Any proposal for the possible incorporation of an additional diagnostic category would systematically, objectively, and comprehensively review the evidence in the literature on all of these different factors. This process is described in more detail elsewhere (6).

At the same time, there are other important factors and considerations. Given the importance of international communication, new diagnoses that are already included in *ICD-10* will, all other things being equal, have a much better chance of inclusion in *DSM-IV* than will new diagnoses that are not mentioned in *ICD-10.* On the other hand, new diagnoses that are subject to controversy and/or possible misuse will require especially strong empirical support. Insofar as possible, we will attempt to avoid controversies by including only those new diagnoses that command widespread empirical and clinical support. While the major goal of *DSM-IV* is clinical, research, and educational utility, we will be especially cautious about new diagnoses that might be stigmatizing or have an adverse forensic impact. New diagnoses that will dramatically affect the overall prevalence of mental disorders will also be carefully scrutinized.

Before including a suggested new diagnosis, we are attempting to gather empirical data through either field trials or data reanalyses to determine its likely impact. We will determine which existing categories most overlap with the diagnosis in question, and whether the suggested new diagnosis can be better included as a specific example in the "not otherwise specified" category. There are no infallible rules to apply. Ultimately, we must exercise careful clinical judgment and common sense in the context of a comprehensive awareness of the empirical data relevant to a particular issue.

## ILLUSTRATIONS

We have chosen from among the many proposed new diagnoses for *DSM-IV* three different examples. These suggestions provide an opportunity to give concrete examples of the many factors that must be balanced in making these decisions and of the different degrees of evidence available for different categories.

### *Acute Stress Disorder*

A review of the literature has highlighted the possible usefulness of including acute stress disorder (which some have termed "brief reactive dissociative disorder") as a separate and distinct category (7). This diagnostic category would describe the immediate psychological consequences of major stress and might help to fill a nosologic gap between posttraumatic stress disorder and adjustment disorder. Acute stress disorder is currently included in the *ICD-10* diagnostic criteria for research; the diagnosis is given to individuals who have been exposed to an exceptional medical or physical stressor and have experienced the immediate onset of anxious and dissociative symptoms which have abated relatively promptly. One potential adverse consequence of this diagnostic category is that a relatively large proportion of disaster victims would be labeled as having a mental disorder, however transitory and free of stigma it might be. The availability of this diagnosis would be useful in early case finding and preventive efforts.

To learn more about the prevalence, impairment, predictive power, and optimal definition of acute stress disorder, a series of questions has been systematically applied to five different sets of data collected on individuals who have recently experienced man-made or natural disasters. The John D. and Catherine T. MacArthur Foundation has sponsored analyses of these data sets and a number of other analyses of data sets for *DSM-IV*. Evaluating proposed sets of diagnostic criteria against a series of already existing data sets is a novel approach and has been an exciting and important step in the *DSM-IV* process of empirical review. Extensive evidence supporting the existence of acute stress disorder and its inclusion in *ICD-10* make it likely that this diagnostic category will ultimately be incorporated in *DSM-IV*.

### *Mixed Anxiety/Depression and Minor Depression*

A series of literature reviews suggest that individuals are frequently encountered in outpatient, primary care, and community samples who do not meet the full criteria for depression but who do have symptoms of depression, perhaps combined with symptoms of anxiety (8–12). There is evidence that such individuals have a clinically significant level of impairment which is equivalent to that associated with many nonpsychiatric illnesses. The absence of these disorders from the nomenclature may lead to failure to identify people who manifest these syndromes, particularly in outpatient and primary care settings, and consequently to their incomplete diagnosis and treatment. *ICD-10* includes a mixed anxiety/depressive disorder for individuals who fail to meet existing definitions of syndromal levels of either kind of disorder.

It is possible that mixed anxiety/depression and minor depression are highly prevalent. Inclusion of these disorders in the nomenclature, in diagnostic algorithms, and in semistructured interviews might greatly increase the apparent overall prevalence of mood and anxiety disorders, and in turn, of all mental disorders. There is no inherent problem in high prevalences of disorders—witness the high rates of hypercholesterolemia and obesity as these have been generally defined in our population—so long as it is clear that the threshold established is associated with clinically significant distress and/or disability and that the category is useful in predicting prognosis and guiding treatment. There are few data, however, concerning the treatment implications or other validators of mixed anxiety/depression and minor depression. The concern with mixed anxiety/depression and minor depression, then, is that we might create a whole cohort of new patients without sufficient evidence that their identification as patients provides useful information for improving treatment.

To help clarify these issues, we are conducting a field trial to determine the prevalence, impairment, optimal definition, and overlap of mixed anxiety/depression and minor depression in primary care settings. This will also help to settle the question of the degree to which the high prevalence of "subthreshold" patients in primary care is a function of differences in the quality of diagnostic assessment. While the field trial will clarify many questions, a cross-sectional field trial will not be able to provide data on the treatment implications, course, or prognosis for these diagnostic categories. One possible compromise would be a clear description of these syndromes in the "not otherwise specified" text and the presentation of potential sets of criteria in the *DSM-IV Sourcebook* or the appendix to *DSM-IV*.

### *Sadistic Personality Disorder*

Sadistic personality disorder, which was included in the *DSM-III-R* appendix of categories needing further study, is an example of a proposed category that will not be included in *DSM-IV*. A review of both published literature and unpublished findings in this area (13) has uncovered few if any studies on the prevalence, phenomenology, sex bias, descriptive and external validators, and possible misuse of this diagnostic category. One survey of clinicians has suggested that there would be considerable overlap between this category and other axis II categories and that clinicians and researchers would rarely use the category. The lack of any empirical support and historical tradition for this category as well as any compatibility with *ICD-10* makes it impossible to recommend it for inclusion in *DSM-IV*.

## CONCLUSIONS

Modifying the diagnostic manual in any way has tremendous conceptual and practical implications. These implications are magnified when the modifications involve the addition or deletion of whole diagnostic categories. We have tried in this article to share some of these practical and conceptual considerations. The addition or deletion of diagnostic categories reflects our beliefs about what constitutes a mental disorder and how mental disorders can best be organized.

It is to be hoped that future systems, *DSM-V* and beyond, will be based on a much more profound understanding of mental disorders than is currently possible. With the availability of increased knowledge, many of our current diagnostic conventions will undoubtedly become much less pertinent. We can look forward to future diagnostic systems based on pathogenetic understanding, rather than more superficial descriptive similarities, which will be both more elegantly clear and more powerfully predictive. Diagnostic categories will be more specific, better validated, and less heterogeneous. In such an environment, many of the present diagnoses will no doubt be retired as interesting historical relics that reflect our current relatively naive understanding.

# Abnormal Intracellular Calcium Ion Concentration in Platelets and Lymphocytes of Bipolar Patients

Steven L. Dubovsky, M.D., James Murphy, Ph.D., Marshall Thomas, M.D., and Jonella Rademacher, B.S.

*The authors measured intracellular $Ca^{2+}$ concentrations in four manic and five bipolar depressed patients and seven comparison subjects. Platelet and lymphocyte intracellular $Ca^{2+}$ concentrations were comparable. The patients' mean intracellular $Ca^{2+}$ concentrations were higher than those of the comparison subjects and demonstrated more interindividual variation. These findings suggest a diffuse abnormality in mechanisms affecting intracellular calcium homeostasis in bipolar disorder.*

(Am J Psychiatry 1992; 149:118–120)

In the last several years there has been interest in the possible role of the membrane phosphatidylinositol (PI) and calcium ion ($Ca^{2+}$) second messengers in bipolar affective disorders. Because increases in free intracellular $Ca^{2+}$ concentration ($[Ca^{2+}]_i$) generated by PI turnover and $Ca^{2+}$ influx regulate neuronal function in a manner similar to that of blood platelets (1) and lymphocytes (2), it may be possible to use such cells as markers of changes in the brain. In addition, if hyperactivity of these signaling mechanisms were observed in more than one type of peripheral cell, it might suggest a generalized shift in cellular dynamics that is related to the hyperactive physiology of many bipolar states.

Previous reports suggested higher resting and agonist-stimulated $[Ca^{2+}]_i$ in blood platelets of untreated manic patients (3) and bipolar depressed patients (3, 4) than in comparison subjects. In the present study we used Fura 2, a calcium-chelating fluorescent intracellular $Ca^{2+}$-binding dye, to test the hypothesis that high $[Ca^{2+}]_i$ in lymphocytes could also be demonstrated. A positive result would suggest that patients with mood disorders have an abnormality in $Ca^{2+}$ signaling in two different kinds of cells in which a variety of other abnormalities have been reported.

## METHOD

### *Subjects*

Nine normotensive bipolar patients and seven comparison subjects participated in the study. Informed consent was obtained from all subjects. The nine bipolar patients had not received treatment or used alcohol or street drugs for at least 3 months. Four had current episodes of mania (two men and two women; mean age=32.8 years, range=21–45 years), and five had depression with past histories of mania (two men and three women; mean age=37.3 years, range=25–48 years). We compared these patients with seven normotensive subjects without personal histories of psychiatric disorders or first-degree relatives with such histories (five men and two women; mean age=36.4 years, range=22–50 years). The patients were diagnosed according to *DSM-III-R* criteria by means of semistructured interviews given by two experienced clinicians (S.L.D. and M.T.).

### *Procedure*

The measurements were all made during the same time of year. At 9:00 a.m. 80–100 ml of blood was

drawn into 1/6 volume acid citrate dextrose anticoagulant containing 100 μM of aspirin, and it was prepared as described previously (3, 4). Briefly, centrifugation of platelet-rich plasma yielded platelet-poor plasma and a platelet pellet that was resuspended in Ringer's citrate buffer with apyrase. The suspension was centrifuged for 10 minutes at 570 *g*, and the platelets ($0.5\times10^9$ cells/liter) were resuspended in HEPES buffer with EGTA and $CaCl_2$ (final $[Ca^{2+}]_i$=1.0 mM). Aliquots of 1.2 ml were incubated with either 1 μM of Fura 2-acetoxymethyl ester (Fura 2-AM) or, to measure cell autofluorescence, an equivalent volume of dimethylsulfoxide (DMSO).

To the platelet-poor plasma was added 6% dextran (molecular weight=500,000), and the volume was adjusted to 50 ml with 0.9% saline. After erythrocyte sedimentation, leukocyte-rich plasma was centrifuged at 275 *g* for 6 minutes. The pellet was resuspended in 2 ml of platelet-poor plasma per 50 cc of original blood and underlayed in polypropylene tubes first with 42% and then with 51% Percoll in platelet-poor plasma. After centrifugation for 11 minutes at 275 *g*, mononuclear cells were removed, washed once in platelet-poor plasma, resuspended in the HEPES medium, and placed in tissue culture plates to remove monocytes. Lymphocyte concentration was adjusted to $1\times10^9$ cells/liter of HEPES. Aliquots of 1.2 ml were then incubated for 60 minutes with either Fura 2-AM or DMSO as already described.

After incubation with Fura 2-AM, platelets and lymphocytes in random order were re-pelleted to remove external dye and resuspended in the HEPES medium. Fluorescence was measured at 37 °C on a Perkin Elmer LS5B fluorimeter by using excitation wavelengths of 340 and 380 nm and an emission wavelength of 498 nm. After subtracting cell autofluorescence and manganese quench of fluorescence from the Fura 2 that leaked out of the cell and bound $Ca^{2+}$ in the medium, we calculated $[Ca^{2+}]_i$ according to the method of Grynkiewicz et al. (3–5). Determinations were usually performed in duplicate, and the mean value was used. The interassay variability was <5% to 7%.

### *Statistical Analysis*

Using the SAS-PROC GLM computer program, we conducted a repeated measures analysis of variance with cell type (platelet, lymphocyte) as the repeated factor and diagnostic group (comparison, bipolar) as the fixed effect. Interindividual variations in $[Ca^{2+}]_i$ in the bipolar patients and comparison subjects were compared by determining F ratios of the two groups' standard deviations for $[Ca^{2+}]_i$ in platelets and $[Ca^{2+}]_i$ in lymphocytes.

## RESULTS

**TABLE 1. Intracellular Calcium Ion Concentrations in Lymphocytes and Platelets of Bipolar Patients and Comparison Subjects**

| | Intracellular $Ca^{2+}$ Concentration (nM) | |
|---|---|---|
| Subject | Platelet | Lymphocyte |
| Bipolar patients | | |
| 1 | 103 | 104 |
| 2 | 118 | 122 |
| 3 | 160 | 147 |
| 4 | 97 | 102 |
| 5 | 141 | 193 |
| 6 | 104 | 99 |
| 7 | 152 | 159 |
| 8 | 112 | 129 |
| 9 | 102 | 103 |
| Mean | 121 | 129 |
| SD | 23.8 | 32.2 |
| Comparison subjects | | |
| 1 | 84 | 84 |
| 2 | 83 | 93 |
| 3 | 79 | 82 |
| 4 | 83 | 86 |
| 5 | 88 | 88 |
| 6 | 71 | 69 |
| 7 | 63 | 77 |
| Mean | 79 | 83 |
| SD | 8.7 | 7.8 |

As shown in table 1, there was no significant interaction between group and cell type (F=0.25, df=1, 14, p≤0.62) (i.e., no significant difference between platelet and lymphocyte $[Ca^{2+}]_i$ in the comparison subjects and bipolar patients) and no significant difference between platelet and lymphocyte $[Ca^{2+}]_i$ (F=2.54, df=1, 14, p≤0.13). The platelet and lymphocyte $[Ca^{2+}]_i$ values were nearly identical in most individuals, supporting the reliability of the assay. On the other hand, there was a large and significant difference between the comparison and bipolar subjects (F=17.69, df=1, 14, p≤0.0009); $Ca^{2+}{}_i$ in both platelets and lymphocytes was on average 1.5 times as high in the bipolar subjects as in the comparison subjects. Every $[Ca^{2+}]_i$ measure for the individual bipolar patients was more than two standard deviations above the mean for the comparison subjects. There was greater interindividual variation of $[Ca^{2+}]_i$ in the patients than in the comparison subjects for both platelets (F=7.48, df=8, 6, p≤0.03) and lymphocytes (F=17.04, df=8, 6, p≤0.005).

## DISCUSSION

The finding of higher lymphocyte $[Ca^{2+}]_i$ in bipolar patients than in healthy subjects extends previous findings about $[Ca^{2+}]_i$ in platelets (3, 4) and raises several new issues. First, it may now be appropriate for investigators in other laboratories to attempt replication with either type of cell. In view of the greater heterogeneity of lymphocyte and platelet $[Ca^{2+}]_i$ in bipolar patients, which probably reflects their clinical and possibly genetic heterogeneity, some populations may be more likely to demonstrate this abnormality than others. Second, similar hyperactivity of the intracellular $Ca^{2+}$ signal in unrelated peripheral cells could imply a generalized abnormality of the cell membrane, a G-protein, or other mechanism of intracellular $Ca^{2+}$ homeostasis in bipolar illness that could extend to brain neurons. In contrast, a study of hypertensive subjects (6) showed high $[Ca^{2+}]_i$ in platelets but not lymphocytes, suggesting a more circumscribed abnormality, perhaps related only to vasomotor instability.

Another implication is that impairment of various in vitro aspects of lymphocyte mitogenesis and cytotoxicity that have been reported in depression (7) and mania (Z. Kronfol and J.D. House, unpublished data, 1989) could be related to an abnormality of intracellular $Ca^{2+}$ signaling. Although a moderate increase in $[Ca^{2+}]_i$ initiates lymphocyte proliferation (8), excessive increases can directly inhibit lymphocyte activity (9). Elevated resting $[Ca^{2+}]_i$ could also impair lymphocyte function by activating a $Ca^{2+}$/calmodulin-dependent phosphodiesterase not normally present in the quiescent state that inhibits further cellular activity by hydrolyzing cyclic nucleotides (8). Increased activation of suppressor T cells by a heightened intracellular $Ca^{2+}$ signal is another possible mechanism of reduction of the overall lymphocyte response.

Caution is necessary, however, in drawing such conclusions. We did not measure lymphocyte function and therefore cannot correlate this with $[Ca^{2+}]_i$. In addition, the hyperactive $Ca^{2+}$ signal may be derived from a subgroup of lymphocytes and have limited implications for the entire population of cells. Although our patients were free of medication and other substances long enough for a new generation of platelets and lymphocytes to have been formed, it is also conceivable that previous experience with these or other substances could somehow have affected stem cells. A more relevant concern is that high $[Ca^{2+}]_i$ could be a marker of severity or some other clinical characteristic, rather than bipolarity. Further studies might address these issues by correlating $[Ca^{2+}]_i$ in lymphocyte subpopulations with discrete measures of lymphocyte function in patients in whom severity, episode frequency, and other potentially relevant clinical factors are controlled.

# Verapamil Versus Lithium in Acute Mania

Enrique S. Garza-Treviño, M.D., John E. Overall, Ph.D., and Leo E. Hollister, M.D.

---

*Twenty acutely manic patients were studied in a double-blind randomized trial comparing verapamil with lithium. The Petterson Mania Scale, the Brief Psychiatric Rating Scale (BPRS), and the Clinical Global Impression (CGI) were administered before treatment and weekly during 4 weeks of treatment to evaluate response to verapamil and lithium. Both treatment groups improved significantly, and there were no significant overall differences between treatments.*

(Am J Psychiatry 1992; 149:121–122)

---

Lithium is the standard treatment for acute manic episodes, but 20%–40% of patients do not respond well, and side effects impair many patients (1). Lithium may affect calcium metabolism, and patients with bipolar disorder may have abnormalities in calcium metabolism as a characteristic of this disorder (2). The efficacy of verapamil in the treatment of mania has been examined in several small open studies and one double-blind study involving fewer than 10 patients (3, 4).

## METHOD

This study was conducted at a 250-bed hospital. Included were newly hospitalized patients meeting *DSM-III-R* criteria for an acute manic episode. Pregnant women were excluded, as were patients in whom verapamil or lithium was contraindicated. Also excluded were patients treated recently with depot neuroleptics. Patients were evaluated with the Clinical Global Impression (CGI) (5), the Petterson Mania Scale (6), and the Brief Psychiatric Rating Scale (BPRS) (7) before treatment (baseline) and weekly for 4 weeks of treatment.

Twelve patients who were given verapamil finished the protocol; there were four men and eight women in this group, and their median age was 33 years. Eight patients who were given lithium finished the protocol; there was one man and seven women in this group; their median age was 34.

Medications were packaged as identical-appearing capsules containing 80 mg of verapamil or 300 mg of lithium carbonate. Verapamil doses were titrated from 80 mg b.i.d. the first day, 80 mg t.i.d. for the next 2 days, and then 80 mg q.i.d. for the remainder of the study. The initial lithium dose was 0.5 meq/kg; subsequent doses were adjusted to maintain blood levels in the range of 0.75 to 1.5 meq/liter.

The study medications were packaged and dispensed by a pharmacist according to a randomization list maintained in the pharmacy. One physician managed clinical care and monitored lithium blood levels, ensuring that the blind rater (E.S.G-T.) had access to no information that could lead to identification of the treatment.

## RESULTS

Unadjusted mean Petterson Mania Scale scores and CGI severity scores at baseline and covariance-adjusted mean scores for the 4 weeks of drug treatment are presented in table 1. With the exception of pretreatment values, the standard deviations in each section of the table are square roots of the error mean squares from the analysis of covariance (ANCOVA). These are provided because raw standard deviations do not convey the appropriate error variability for comparison of means after correction for baseline differences (8, 9).

Patients assigned to the verapamil group were more disturbed at baseline than were patients in the lithium group. Primary analyses were therefore baseline-covaried ANCOVA. Both groups improved significantly on the four measures ($p<0.01$). The groups did not differ significantly in the magnitude of treatment-induced change. We also analyzed the change in scores before and after treatment in addition to ANCOVA-adjusted measures. Even though those results should reflect in part the significant or near significant baseline differences in this randomized study, none of the simple com-

**TABLE 1. Scores on the Petterson Mania Scale and the CGI for Acutely Manic Patients Given Verapamil or Lithium**

| Test and Time | Mean Score: Patients Given Verapamil (N=12)[a] | Mean Score: Patients Given Lithium (N=8)[a] | p | SD[b] |
|---|---|---|---|---|
| Petterson Mania Scale[c] | | | | |
| Before treatment | 23.92 | 20.38 | 0.08 | 4.23 |
| Week 1 | 19.25 | 18.87 | 0.82 | 3.20 |
| Week 2 | 17.29 | 16.75 | 0.90 | 5.09 |
| Week 3 | 14.75 | 16.12 | 0.47 | 3.72 |
| Week 4 | 13.29 | 12.39 | 0.30 | 2.97 |
| CGI severity score[d] | | | | |
| Before treatment | 5.33 | 4.38 | 0.03 | 0.90 |
| Week 1 | 4.49 | 4.14 | 0.21 | 0.51 |
| Week 2 | 4.07 | 4.28 | 0.65 | 0.87 |
| Week 3 | 3.91 | 3.64 | 0.53 | 0.81 |
| Week 4 | 3.53 | 2.96 | 0.34 | 1.27 |

[a] The means for the baseline values are raw means; the means for the treatment weeks are adjusted for covariance.

[b] With the exception of pretreatment values, the standard deviations are square roots of the error mean squares from the analysis of covariance.

[c] Difference across weeks: drugs, p=0.89; pattern, p=0.38.

[d] Difference across weeks: drugs, p=0.48; pattern, p=0.57.

parisons of changes in scores before and after treatment approached statistical significance (p<0.20).

In a repeated measures design, reliability in discriminating differences within patients over time and reliability in discriminating true differences between patients in a cross-section of time are important. A pooled within-patient correlation matrix with communality estimates in its diagonal was subjected to a principal axes factor analysis, and squared loadings on the first common factor of the 4×4 within-patient correlation matrix were calculated as lower bound reliability estimates. A similar procedure was used to discriminate between individuals with different levels of global severity in a cross-section of time. A pooled within-weeks correlation matrix was calculated by combining the covariances among the four measures calculated across patients separately for each week. The within-patient reliability estimates for the Petterson Mania Scale, BPRS, and CGI severity scores were 0.74, 0.61, and 0.72, respectively. The between-patient reliability estimates were 0.62 (Petterson Mania Scale), 0.70 (BPRS total score), and 0.77 (CGI severity).

The two groups were comparable in terms of number of side effects. One patient in the verapamil treatment group developed constipation, and two patients in the lithium treatment group suffered nausea and vomiting. Three initially randomized patients were dropped from the lithium protocol: one because of cardiotoxicity and another because of assaultive behavior. The third lithium patient withdrew voluntarily, accounting for the reduced size of that group. More patients in the verapamil group received a combination of 5 mg of haloperidol and 2–4 mg of lorazepam for optimal control of excessive agitation (10). Seven patients out of 12 in the verapamil group and four of the eight lithium patients received a combination of haloperidol and lorazepam for control of excessive agitation. Three of the verapamil patients accounted for most of the neuroleptic-hypnotic use.

## DISCUSSION

The difference between treatment groups that was present at baseline in spite of random assignment complicates interpretation of differences in treatment effects. If one examines unadjusted raw scores (not shown), the verapamil group evidenced greater absolute change from baseline to endpoint. If one examines the covariance-adjusted means (table 1), the trend in symptom reduction across weeks favors lithium over verapamil. However, there was no statistically significant difference between the groups in either case, and both treatment groups improved significantly. In spite of the absence of a placebo control group in this study, the rate of symptom reduction in both treatment groups is indicative of a treatment effect. On this basis, we conclude that the results add to the evidence that verapamil is effective in treating some patients with manic conditions. Larger studies should be undertaken to determine whether verapamil may be effective in patients who fail to respond well to lithium.

# What Is Meant by the Term "Binge"?

**Sarah J. Beglin, M.A., and Christopher G. Fairburn, D.M.**

*Systematic examination of the use of the word "binge" by 243 young women revealed discrepancies between the lay and technical uses of the term; the young women placed great emphasis on loss of control and less on the quantity eaten. These discrepancies indicate that the term "binge" should be clearly defined in clinical practice.*

(Am J Psychiatry 1992; 149:123–124)

In view of the high prevalence of eating disorders among young women in general, and among young female psychiatric patients in particular, female patients in this age group need to be asked as a matter of routine about binge eating. For this reason the term "binge" must be included in every psychiatrist's lexicon.

Like many technical terms in psychiatry, the word "binge" is also in general use. This dual use is a potential source of confusion. The focus of this paper is on the use of the word "binge" by young women in the community. Such use needs to be understood if responses to questions about binge eating are to be interpreted correctly. We conducted two studies. The aim of the main study was to examine how young women apply the term to their own eating. The aim of the supplementary study was to determine what young women understand the term to mean.

## METHOD

The source sample consisted of 285 women, aged 16 to 35 years, who were selected at random from the case registers of two family practices. One practice was in a suburban area, and the other served a rural population. Of the 285 subjects, 243 (85%) agreed to take part. Their mean±SD age was 26.6±5.5 years. Sixty percent were married, and 4% were separated or divorced. The social class distribution was as follows: 3% in class I, 26% in class II, 44% in class III, 13% in class IV, and 3% in class V; 8% were full-time students, and the class of 3% was unknown.

Subjects who agreed to take part underwent a research interview that included the Eating Disorder Examination, a widely used measure of the eating habits and attitudes characteristic of people with eating disorders (1). The Eating Disorder Examination distinguishes four forms of overeating: objective bulimic episodes, subjective bulimic episodes, episodes of objective overeating, and episodes of subjective overeating. These are mutually exclusive, although it is not uncommon for subjects to report episodes of more than one type. The distinction between the four types is based on the presence or absence of two features, loss of control during the episode (required for both types of bulimic episode) and the consumption of a large amount of food (required for objective bulimic episodes and episodes of objective overeating). Loss of control is considered present if the subject would have had difficulty either in preventing the episode of overeating from starting or in stopping it once it had started. The amount eaten is considered large when it clearly exceeds the quantity that would usually be eaten under the circumstances.

For the purpose of the present study, questions about the term "binge eating" were added to the Eating Disorder Examination. Subjects who had experienced recent episodes of overeating were asked to specify which they considered to be binges. In this way it was possible to add individual subjects' use of this term to the classification provided by the Eating Disorder Examination.

A small supplementary study was conducted to shed light on the use of the term "binge." The subjects were a subset (N=40) of the entire sample of 243 women. They did not differ from the remainder in their demographic or clinical features. Each of these women was first asked what she understood by the term "binge," and her answers were classified on the basis of the presence or absence of 11 features said to characterize

binges. Then, each one of the 11 features was reviewed and the subject was asked if it was, or was not, characteristic of binges.

## RESULTS

Many of the 243 subjects reported recent episodes of overeating. Over the preceding 28 days, 22 (9%) had experienced objective bulimic episodes, 47 (19%) had had episodes of objective overeating, 19 (8%) had had subjective bulimic episodes, and 107 (44%) had had episodes of subjective overeating. The proportions of the episodes of these four forms of overeating that the subjects classified as binges were as follows: objective bulimic episodes, 83%; episodes of objective overeating, 19%; subjective bulimic episodes, 42%; and episodes of subjective overeating, 13%. Thus, few of the episodes of objective overeating were classified as binges, despite the large amount of food eaten, whereas nearly one-half of the subjective bulimic episodes were so classified, even though the amount eaten could not be regarded as large. This indicates that the subjects placed great emphasis on loss of control (as defined by the Eating Disorder Examination) and less on the quantity eaten.

In the supplementary study, when the subjects were not prompted, the only feature on which there was consensus was that a binge involves the consumption of a large amount of food. When prompted, most subjects had definite opinions on which of the 11 features characterize a binge, but this certainty was associated with little agreement on the features themselves. There were four exceptions. At least three-quarters of the subjects thought that the following features are required for episodes of eating to be classified as binges: eating a large amount of food (N=37, 93%), extreme fullness (N=33, 83%), a sense of loss of control (N=36, 90%), and subsequent dysphoric mood (N=30, 75%).

## DISCUSSION

The definition of "binge" has changed since its original inclusion in *DSM-III*. There the definition was "rapid consumption of a large amount of food in a discrete period of time, usually less than two hours." In *DSM-III-R*, the suggested 2-hour limit was dropped. In the provisional *DSM-IV* scheme, a more radical change is proposed: loss of control is required (2). The provisional definition is as follows:

> An episode of binge eating is characterized by both:
> i. eating, in a discrete period of time (e.g., in any two-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time; and,
> ii. a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).

This is essentially the definition of an objective bulimic episode used in the Eating Disorder Examination.

Our two studies allowed a comparison of the technical use of the term "binge" with the definition used by a community sample of young adult women. When the young women were asked to apply the term to their own behavior, it emerged that they placed great emphasis on loss of control and somewhat less on the quantity of food eaten. The former use is in line with the provisional *DSM-IV* definition, but the latter is not.

The findings of the supplementary study suggest that when young women are asked on self-report questionnaires about binge eating (undefined), their responses simply refer to episodes of perceived overeating. However, further questioning of our subjects revealed that binge eating was regarded as a particular form of overeating, in which a large amount of food is eaten with a sense of loss of control and subsequent fullness and dysphoria.

Our subjects were young women in England, and one may therefore ask whether similar findings would have emerged had the study taken place in the United States. However, even if the study had used a North American sample, questions would arise about the generalizability of the findings, since there may well be regional and subcultural differences in the use of the term. The point at issue is not the identification of exactly how the word "binge" is used within a particular subgroup but rather the demonstration, with a relevant sample, that there are discrepancies between the lay and technical uses of the term.

The implication of the findings for clinical practice and research is clear. When the term "binge" is used in a professional context, a clear, unambiguous definition must be provided.

### GENDER ISSUES

**Women's Progress: Promises and Problems,** *edited by Jeanne Spurlock, M.D., and Carolyn B. Robinowitz, M.D. New York, Plenum, 1990, 258 pp., $39.50.*

This multiauthored book is one of a series entitled Women in Context: Development and Stresses. Each volume is edited by well-respected women academics. As each book appears, it begins to fill the void in authoritative literature on contemporary women's development and experience.

This particular book's focus is mainly on aspects of mothering, although the focus is unstated and several chapters seem not to belong to the mothering theme.

The first chapter, by Adams and Adams, examines family structures and the definition of "family" in different historical periods. It is important to recognize that this definition is fluid and that obstacles to the autonomy of women, erected to preserve "family" values, may come from idiosyncratic views of what a family is.

Spurlock's chapter on singleness touches only briefly on the plight of the single mother; rather, it addresses the myths surrounding women who do not marry. An interesting chapter on foster families highlights the fact that the mothering role is more difficult and less rewarding for foster mothers than it is for the majority of women.

Rogoff-Thompson and Thompson discuss the changing face of adoption in the United States, emphasizing the underlying theme of loss. Birth parents lose a child through adoption; adoptive parents lose the dream of a child born of them. Both sets of parents go through a process of grief and adaptation. Kim adds a chapter on transcultural and transracial adoption, an increasingly prevalent phenomenon. Few longitudinal studies are available to compare the development of transculturally or transracially adopted children with more conventionally adopted children.

Ruth Fuller addresses the problems of working mothers, who currently account for more than half of all mothers. She cites a 1988 review which concluded that maternal employment per se is not significantly related to children's development.

Two chapters discuss the special problems of mothers of disabled children. The personal account of Mary Akerley is particularly informative. There is also an important chapter on mothers who abuse their children, which concludes that the profile of the abusing mother remains poorly articulated.

Three chapters on women offenders, battered women, and homeless women are only peripherally connected to the mothering theme, although crucial to women's experience. Hutchinson's paper on battered women asserts that "pregnancy seems to unleash the deepest and most intense antifemale feelings that the man has." She goes on to delineate specific recommendations for intervention strategies with battered women.

The final chapter is on transsexualism and the female transsexual, an issue that seems out of keeping with the rest of the volume. On the other hand, a chapter by Kirkpatrick on homosexuality and parenting is scholarly, important, and relevant. Between 200,000 and 3,000,000 children in the United States are being brought up by lesbian mothers. For these women, motherhood is the most salient feature of their self-concept. With respect to outcome of lesbian child rearing, comparison studies appear to indicate that the presence or absence of a second adult who is available to the child is the most significant determinant of outcome. Coupled mothers, lesbian or heterosexual, seem to respond to children's needs more readily than do single mothers. This hypothesis needs repeated testing, but the preliminary results presented by Kirkpatrick are important.

In summary, this book provides a new synthesis of contemporary findings about women in different family configurations and reflects on the challenges and determinants of effective mothering. Insofar as some of the chapters do not adhere to this major theme, the book reads somewhat disjointedly and disappointingly.

*Toronto, Ont., Canada*

**Feminism and Psychoanalytic Theory,** *by Nancy J. Chodorow. New Haven, Conn., Yale University Press, 1989, 273 pp., $25.00.*

This volume represents a synthesis of Nancy Chodorow's thinking as it has evolved from the early 1970s until today. Chodorow traces her early feminist origins and her evolving interest in psychoanalysis, citing the influences of psychoanalysts like Horney, Klein, Mahler, Winnicott, and Loewald.

As a psychoanalytic feminist, Chodorow offers an incisive critique and a penetrating analysis of this perspective. She also acknowledges that "psychoanalytic feminism has not been especially attuned to differences among women—to class, racial, and ethnic variations in experience, identity, or location in social practices and relations" (p. 4).

Her thinking about the etiology of male dominance has shifted over the years from the view that women's mothering was the cause of male dominance to an understanding of it as a complex and multidetermined phenomenon, varying with psychological, cultural, and social constructions of gender. She does indicate, however, that the experience of the powerful mother is a core factor in "the virulence of masculine anger, fear, and resentment of women, or of aggression toward them" (p. 6). Although she does not negate the powerful influence of the father on psychological development, she does not believe that he is the predominant influence.

From a theoretical perspective, Chodorow also focuses on the importance of the development of the self as it differs for men and women. In her conceptualization of object relations, she adds complexity to the feminist view of gender.

The first section of the book consists of four essays from the early- to the mid-1970s under the title The Significance of

Women's Mothering for Gender Personality and Gender Relations. In this section, Chodorow develops her thinking about the significance of women's mothering, describing mother-daughter and mother-son relationships and the impact of mothering on feelings about women and men. She considers the socialization of males and females from a cross-cultural perspective. She argues that through their relationship to their mother, women develop what is called a self-in-relation and men a self that, she states, denies relatedness.

The second section of the book, entitled Gender, Self, and Social Theory, draws on object relations theory and looks at the qualities of self that may be not gender-related. Chodorow also examines and critiques the psychoanalytic sociologists Marcuse and Brown.

In the final section of the book, Psychoanalysis, Psychoanalysts, and Feminism, Chodorow describes psychoanalytic feminism from a number of perspectives, culminating in an essay entitled "Seventies Questions for Thirties Women: Gender and Generation in the Study of Early Women Psychoanalysts." In this she reports her interviews of early women psychoanalysts, trained between the 1920s and early 1940s, whom she interviewed in the early 1980s. These women reveal less gender orientation in their direct responses than they did in the lives they led. They did not see gender as a particularly salient variable, nor did they think they were challenging basic notions of women's nature in their quest for psychoanalytic careers, despite prevailing theoretical perspectives that would have suggested different lives for them.

In this rich and varied but intense and tightly reasoned volume, Chodorow brings us up-to-date on a range of contemporary psychoanalytic thinking in an area that is often not so available in the psychoanalytic literature. Her carefully constructed arguments define the subject and explicate her point of view, but she is not so tightly bound to one theoretical posture that she cannot attend to others. The book is a substantial work, to be read carefully by those interested in psychoanalytic thinking and practice.

*Boston, Mass.*

**Making a Difference: Psychology and the Construction of Gender,** *edited by Rachel T. Hare-Mustin and Jeanne Marecek. New Haven, Conn., Yale University Press, 1990, 201 pp., $18.95.*

The difference in the title of this book refers to gender. The difference is twofold. The anatomical-biological difference is relatively fixed, but the meaning and representation of gender is subject to psychological and sociological influence. The social roles of men and women and the expectations of them are affected by cultural attitudes. There are roughly two approaches to the issue. One emphasizes the differences between male and female; the other tends to minimize it. Although each position, in the extreme, is fallacious, both have fostered the examination of the meaning attributed to sexual and gender differences by highlighting the issues. The stereotypes associated with maleness and femaleness abound in paradox and contradiction. The stereotypes are permeated with the implication that maleness is superior to femaleness. Even admirable characteristics that are considered feminine, like nurturance, caring, and intuitiveness, are denigrated in favor of the masculine traits of competitiveness, rationality, and assertiveness.

A major focus in feminist psychology has been the elucidation of the differences between males and females. The authors in this book point out that many studies purported to define maleness and femaleness are flawed by gender bias. The studies of sex and gender differences have been inconsistent and unreliable or have been merely descriptive and nonexplanatory, implying a nonmodifiable trait view of behavior, assuming a fixed definition of sex and gender, and disregarding the varieties in meaning associated with levels of organization from the anatomical to the sociological. Attitudes and behaviors associated with maleness and femaleness are not determined by sex alone but are influenced by the complexity of experiences and psychological organization. Both individual and social issues have to be considered.

This book reveals that, instead of focusing on the explication of gender differences, modern feminist researchers and scholars are concerned with the effect on thought and behavior of prevailing assumptions about sex. Definition of sex is a method of categorizing and communicating expectations. The concept of androgyny has been posited as a corrective to the biases that purport to distinguish males and females from each other. Since the concept of androgyny implicitly assumes male and female characteristics as it considers their blending, it does not resolve the dilemma of gender differences, nor does it enhance our understanding of the meaning of gender.

Knowledge does not exist in a vacuum. It is influenced by prevailing cultural modes. In a male-dominated society like ours, concepts congruent with a masculine outlook prevail while issues like relationships, connectedness, and concern with reproduction are considered feminine and are relatively ignored. Parallel with the questions raised about these issues are recent epistemological concerns that impinge on feminist thinking. Among these is the recognition that truth is not absolute and immutable but is contingent on social relations, historical context, and the knower's interests. Criteria of knowledge are not fixed and are multidetermined.

The further development of feminine psychology depends on the recognition that the influences on the development of sexuality in all individuals are diverse, that sexual attitudes are ill-defined and not fixed, and that attributes of what are considered maleness and femaleness are manifested in both sexes. The task of psychological research and study is to delineate the factors that influence this development and the manifestations of these attitudes and behaviors. Although this book is a very helpful guide to the pitfalls to avoid and the directions in which to proceed in the consideration of sexuality, its comprehensiveness would have been enhanced by more consideration of intrapsychic factors involved in the determination of sexuality.

REBECCA Z. SOLOMON, M.D.
*Hartford, Conn.*

**Men and Divorce,** *by Michael F. Myers, M.D. New York, Guilford Press, 1989, 286 pp., $30.00.*

This clinically useful book is the extract of the author's many years of experience in the field of marriage and divorce. Contemporary U.S. society has witnessed increasing dissolution of marriages in recent years. Consequently, there is a need for a better understanding of the impact of separation on the family. In this work, Dr. Myers examines men's experience of the divorce process. His eclectic approach to this task is reflected throughout the book and provides a rich understanding of and a balanced focus on intrapsychic and interpersonal dynamics.

The author's primary goal is to point out that men frequently have difficulty coping with separation. Because they do not directly ask for help, they may express their pain behind a masquerade of self-reliance through somatic problems, alcohol abuse, overwork, and criminal behavior.

*Men and Divorce* is divided into three sections. The first is an overview of historical considerations in marriage and divorce, which sets the stage for the second section, a detailed analysis of different clinical presentations of divorcing men. The third is devoted to therapeutic considerations.

After making a distinction between physical and emotional separations, Dr. Myers critically explores the dynamics underlying the experiences of emotional separation. He tactfully differentiates those separations which are initiated by the husband, those initiated by the wife, and those mutually agreed on because the dynamics and symptoms involved with each may be very different. For example, some men may become involved in several shallow relationships after their wives have initiated separation. This may reflect a defense against intimacy and loss. The true mourning may not actually begin until several months after the physical separation.

Dr. Myers looks at the common experience of many men of finding themselves in the process of separation in a paralyzed position despite their inner conviction that their marriage is over.

Issues related to newly separated men, such as mourning of their lost marriage and adaptation to a new life style, are discussed. The effects of personality, ethnicity, age, and length of marriage on the experience of separation are explored.

Dr. Myers postulates that criminal behavior of abandoned husbands may be triggered in part by the "overwhelming subjective sense of abandonment." Furthermore, he describes the coping strategies of divorcing men with different personality styles, such as overaggressive, passive-aggressive, and passive-dependent.

Other topics discussed are the unique circumstances of divorcing men who are coming out as gay and issues related to divorced fathers and their children.

The last section focuses on treatment strategies and different modes of psychotherapy. These include supportive, behavioral, and insight-oriented approaches. Common themes encountered in treatment, such as anger, dependency, control, grief, male inexpressiveness, loneliness, and isolation, are examined.

The text is easy to read and relatively jargon free, with the added convenience of a brief summary at the end of each chapter. There is also a reference index and a subject index.

This book would appeal as an introductory volume to a broad range of mental health practitioners who work in individual and couples therapy.

MAJID NAFICY, M.D.
*New Haven, Conn.*

## CARING FOR PATIENTS

**Educating Competent and Humane Physicians,** *edited by Hugh C. Hendrie and Camille Lloyd. Bloomington, Indiana University Press, 1990, 240 pp., $29.95.*

One of the special pleasures of reviewing books for the *Journal* is the sensitivity with which the Book Forum Editor selects books that call on the special areas of interest and expertise of a particular reviewer. On occasion, I feel as if I could accuse her of reading my mind and knowing what seems to be of particular concern to me when she forwards a book.

I have been thinking a great deal about the education of competent, compassionate, and humane physicians who understand the new technologies but retain the caring attitudes of past generations. Because of the current economic climate, the need to see many patients quickly, and concern about managed care, it appears as if several factors are converging to discourage young physicians from caring about their patients as complete human beings and to encourage them, instead, to focus their treatment efforts on specific parts of the body.

Drs. Hendrie and Lloyd have edited a volume whose purpose is to address issues of medical education, particularly the necessity for continuing our efforts to train physicians to be professionally competent and yet maintain the personal qualities required to practice comprehensive and humane health care. The book is dedicated to the memory of Dr. Nancy Roeske, Professor of Psychiatry at Indiana University School of Medicine, who died in April 1986. Dr. Roeske was concerned throughout her distinguished professional career about the socialization process of the health professional and the appropriate environment for medical education. Many of the authors in this book were personal friends of Dr. Roeske and share their memories of her with their academic discourses about today's climate of medicine. I, too, counted Nancy among my mentors and friends and was deeply saddened by her untimely death.

The book is divided into four sections. Part one deals for the most part with literature reviews emphasizing the importance of social factors in understanding the pathogenesis of disease and illness behavior and the critical nature of such an understanding in treating patients. In part two the current functioning of medical school settings is reviewed with respect to the current atmosphere, specifically, selection of medical students and training of medical students and residents, with special attention paid to the development of humanistic qualities.

Part three highlights vital programs designed to sensitize physicians in training to the human and humane aspects of medical practice. Particularly interesting in this section is a historical chapter that describes the nineteenth-century women's medical colleges and the efforts of early prominent women physicians to add humaneness and caring to the technological aspects of medical training. This chapter previews current concerns of education in relation to the loss of caring as technology increases and is especially important for psychiatric educators.

In the final section of the book, René Fox, a colleague and friend of Dr. Roeske, echoes some of the themes of previous chapters in a lecture entitled "Training in Caring Competence: The Perennial Problem in North American Medical Education," which she delivered at the Sister Margaret Hospital in Toronto in March 1989.

Throughout the book, as the authors view historical aspects of this problem, they all share a common concern that physicians in the twentieth century improved their technological skills but might have lost their empathic and humanistic skills—that as the science of medicine progresses the art is lost. These authors also note that despite the fact that consciousness has been raised and solutions proposed, the current crop of medical students continues to be woefully deficient in the ability to be compassionate and to understand and integrate biopsychosocial aspects of medical care. They comment that this deficit contributes to the increase in malpractice suits, the public perception of the physician as greedy, and the lack of trust that impedes recovery, even when the technological aspects of medical care are superb.

I was particularly impressed by the chapter by Dr. Roger Bulger, "The Impact of the Educational System on the Development of the Modern Hippocrates." Dr. Bulger makes clear his own biases about the effects of the educational process on the learner. First, he feels that the educational environment is important to the outcome of education. It does matter to the student how people, data, and resources are to be treated. Second, he says that what we do not know far exceeds what we do know, and that a great deal of what we think we know will be shown to be incorrect in the years ahead. Therefore, integrity and humility ought to be encouraged. Third, he feels that the role model of the teacher is far more important than most teachers seem to appreciate and that the analogy between the student-teacher relationship and patient-physician relationship is not lost on students.

Dr. Bulger discusses factors that have led to a deterioration in the student-teacher relationship, including superspecialization, the big business aspects of clinical departments in medical school, and lack of interprofessional education. He concludes his chapter by suggesting, "Paradoxically, if medicine loses some of its lofty financial and social status, it might turn out that those best suited to meet the care needs of our society would continue to seek out places in the profession and to gain entry to our schools." He reminds the reader that in England, despite physicians' overcrowded offices, patients do not feel a loss in quality of care or commitment among physicians. In the United States, perhaps, a smaller, tighter, but more committed army of healers might emerge side-by-side with the scientists and technicians required to manage our extraordinary diagnostic and therapeutic interventions.

*Educating Competent and Humane Physicians* does not propose any sweeping solutions to a very basic and persistent problem in medical education. However, despite the fact that no ultimate solutions are proposed, any thoughtful educator will know that the authors have shared their thoughts, ideas, and experiences and, I hope, have challenged and stimulated the profession to address this perennial problem.

ELISSA P. BENEDEK, M.D.
*Ann Arbor, Mich.*

---

**Institutionalizing Madness: Families, Therapy, and Society,** *by Joel Elizur and Salvador Minuchin. New York, Basic Books, 1989, 251 pp., $24.95.*

The core concern of this book, the dehumanizing force of the mental health system, is indicated in the authors' title *Institutionalizing Madness.* They have chosen consultation to family therapy cases and subsequent follow-up as the path for pursuit of this issue. They conducted a 5-week family therapy seminar and then over the subsequent 5 years followed up the outcome of four families. Through these four families, the authors illustrate their thesis. Their stories draw us into the families, their living circumstances, and their social setting, which includes the special circumstances of kibbutzim in Israel and more ordinary private community settings such as private mental hospitals.

The first story, that of Yoav, is a sad failure. From an attempt at family therapy based on Haley's "leaving home" treatment (1), through increasing institutionalizations, Yoav finally receives a neurological rescue. "Blaming the family" is an important element in this story, and the authors conclude, "Therapy that focuses on the family in isolation is in danger of serving an ideology that values families but resists taking political measures to deal with social factors that overtax them" (p. 62).

The second story is that of Dan, an institutionalized patient in an Israeli hospital. In this story we follow the "consultant" through a series of interventions and/or consultations over 5 years. In this story the therapeutic tactics are revealed as beyond the "structural" Minuchin model. Minuchin uses a variety of other tactics in pursuing his work with this family. This story will be useful for students of family therapy who are developing their own ways and wonder about who to become, and why, in today's mixed up and rich family therapy field.

Joey and Mikey, the subjects of the third and fourth stories, are kibbutzim residents for whom family, school, and community are the important constituent elements. The unfamiliar elements of kibbutz life highlight issues that are similar to the issues faced in our own U.S. society.

In a separate chapter, "Community Management of Mental Illness: An Alternative to Hospitalization," Dr. Mordecai Kaffman includes cases that illustrate his preference for community care rather than inpatient treatment. He makes his points clearly and strongly.

Early in this book Elizur and Minuchin remind us of Jackson's dramatic statement about the "death of the individual" (2). They also include Lyman Wynne's cautionary note about "the individual as subsystem" and remind us that Wynne warned us "not to throw the baby out with the bath water" (p. 63). The authors write compelling stories of their cases, but they might have listened a bit more attentively to Wynne (3) and others. The internal lives of these interesting people remain shadowy at best and are certainly drawn with less intensity than their familial difficulties. Yet Minuchin tells us of his increased sensitivity to individuals due to his father's death in the past and the recent death of his mother. These not only are family events but, as we well know, have profound internal resonations in the individual.

This book, even with these warnings in the middle, remains steadfast in its focus on the outcome of the consultation process and the larger societal context. Certainly family therapy consultants should read this book and wonder about their consultative processes. Yet larger questions are raised for the general practitioner in psychiatry. The deployment of diminishing human services is of increasing concern for all of us. This book raises serious questions about the use of services in the inpatient system as well fragmented resource utilization of outpatient services. It is recommended for the general psychiatric reader as a way of asking unanswered questions about how our field continues to function, relying on hospitalization and fragmentation for some answers and "blaming parents" for others.

The consultative process is often used to provide "answers." This book raises more questions than answers.

**Madness in the Streets: How Psychiatry Abandoned the Mentally Ill,** *by Rael Jean Isaac and Virginia C. Armat. New York, Free Press (Macmillan), 1990, 414 pp., $24.95.*

The major public psychiatric development of the second half of this century has been deinstitutionalization. Deinstitutionalization has two facets, an "emptying" of public psychiatric hospitals of patients and a decreased use of such hospitals as a resource for those who become severely psychiatrically ill. In 1955, there were 559,000 public psychiatric beds. Today there are about 110,000. Factors that are credited or blamed for deinstitutionalization include the following.

1. Public psychiatric hospitals began to have an awful reputation in the later part of the nineteenth century; this reached a peak of notoriety after World War II.
2. In the 1950s the concept developed that institutions themselves caused psychopathology beyond that of the original psychiatric illness.
3. Antipsychotic and antidepressive medications were developed in the 1950s. Of course, these medications have been miraculous in altering the lives of millions, but reliance on these medications alone has become a form of abandonment for patients who need far more services to survive adequately in the community.
4. There was a false notion that communities would readily accept the psychiatrically ill.
5. Government agencies had a decreased sense of responsibility for the psychiatrically ill. From the middle of the nineteenth century until the 1960s, each state had a single agency that was fully responsible for the mentally ill. Federal initiatives changed this in the 1960s, and responsibility was fragmented among federal, state, county, city, and "local control" by the 1970s. Moreover, within each of these governments, further fragmentation developed through a multiplicity of agencies (welfare, vocational rehabilitation, housing, public health clinics, psychiatric clinics) that were responsible for specific services for a given patient. This twofold fragmentation, especially given each public agency's tendency to narrowly define its area of accountability, meant that no public agent was exclusively responsible for the psychiatrically ill.
6. Increased use of the private sector contributed to less use of public institutions. The number of private beds in the United States increased from 36,689 in 1970 to 86,009 in 1986, and there was a vast increase in the number of psychiatrically ill patients who began their treatment in the private sector. Although this was a positive development for the vast majority of the mentally ill, the failure of the private sector to be able to provide for comprehensive long-term care and treatment left some "on the streets."
7. Standards set by the Joint Commission for the Accreditation of Healthcare Organizations and by Medicare contributed to deinstitutionalization in two ways. First, it was easier to meet the standards if an institution had fewer patients to treat. Second, the standards call for patient treatment teams to plan for the patient's discharge on admission.
8. An antipsychiatry mood was launched in the early 1960s with a number of writings (by Szasz, Laing, and Kesey) that questioned the values and motives of psychiatry.
9. Increased legal barriers to treatment came in several forms: the "least restrictive" requirement for the care and treatment of the psychiatrically ill in the 1960s, replacing the need-for-treatment standard for commitment with the dangerousness standard for commitment in the 1960s, time-limited commitments in the 1960s, and the right to refuse treatment in the late 1970s.
10. Right-to-treatment judicial decisions, ironically, were met by serving fewer patients so that the imposed standards could be met.
11. Federal entitlements (551, Medicare, Medicaid, Section 8 housing) enhanced the quality of life for numerous patients, but in addressing only part of a patient's need contributed to the abandonment of total care for some. Furthermore, in the 1980s there were reductions in these programs that further increased the number of abandoned psychiatrically ill individuals.

In summary, a massive and untested public policy was launched in the 1960s, made possible by tested medications. Although there have been thousands and thousands of satisfactory placements of patients in the community and thousands of patients have been successfully treated in clinics and offices, no one is claiming deinstitutionalization is a success story. Part of the problem is simply the word "deinstitutionalization." Severely ill psychiatric patients often need lots of services, and they are poorly served by a negative term that sets the goal in terms of what they do not need. Where shall we place the blame for those mentally ill deinstitutionalized patients who are on the streets? Each of these books has a different answer.

Caton's *Homeless in America* is a concise, clear summary of homelessness in the United States, and she underscores Wyatt and DeRenzo's point that public policies, procedures, and programs should receive the same scientific scrutiny that medications receive (1). Her review of the scientific studies of programs, however, finds slim pickings.

Johnson's *Out of Bedlam,* based on considerable personal clinical experience, highlights inept and malefic government agencies and professionals. She writes that deinstitutionalization was not planned and that it has not saved the taxpayers money. A basic mistake, in her experience, was in thinking that to initiate the process was to complete it. Her solution? She advises that there must be a healing of the split between administrators and practitioners, but her description of both is so negative that it is difficult to believe she really has any hope for change.

Isaac and Armat's *Madness in the Streets* is a scholarly and lively review that goes beyond the need for tested programs and beyond the need for responsive bureaucracies and professions. They make the convincing case that good programs, well-functioning government agencies, and responsible clinicians cannot achieve satisfactory care and treatment of the psychiatrically ill within an antipsychiatry culture. They point out that there is a need for a change in public attitudes from antipsychiatry to a new truth: "that mental illness is a tragic reality requiring protective social intervention" (p. 336). There is a need for another Dorothea Dix.

## PSYCHOANALYSIS

**Freud, Dora, and Vienna 1900,** *by Hannah S. Decker. New York, Free Press, 1991, 284 pp., $22.95.*

This book, by an associate professor of history at the University of Houston, is clearly written and reads relatively easily. It will appeal primarily to those interested in the history of psychoanalysis, and it has a basically polemical thesis. The author attempts to hook up the case of Dora with the political events and prevailing anti-Semitism in Viennese culture in 1900. I did not find her thesis convincing. She writes, " 'Dora' is used in the classroom to assess society's attitude's toward women and the roles it sanctions for them, to study the commingling of familiar pathology and broad-scale malaise, and to illustrate how a psychological illness simultaneously reflects social imperatives" (p. 199). There is considerable overgeneralization of the role of social conditions in trying to explain the case of Dora and a questionable attempt to relate the various prejudices and attitudes of the principal characters in Freud's Dora case to the publications of different well-known Viennese authors at the time.

It is apparently no longer the tradition to teach Freud's case histories to psychiatric residents as it once was; in making presentations at several residency training programs throughout the United States I have learned that a number of them do not offer the residents a chance to study these case histories. In my opinion, this is a tremendous loss for any resident who hopes to go on some day to work with patients in psychotherapy. Freud's case histories are a gold mine of information about psychotherapeutic technique presented by one of the great clinicians of all time and in a manner that is unparalleled in literary style.

Elsewhere (1), I have reviewed the case of Dora from the point of view of learning psychotherapy, and I still believe that it is a masterpiece as well as one of the most important writings on the problem of transference and countertransference. Psychotherapists can learn a great deal from this case. It was, of course, a treatment failure, and I have always believed that one can learn more from one's failures in psychotherapy than one's successes (2). It showed enormous integrity and courage on Freud's part to publish this case, and the history of its publication demonstrates what an intrapsychic struggle Freud must have had before he could get himself to make it public. It remained an unpublished manuscript in his drawer for about 4 or 5 years, and the final version has a number of errors and inconsistencies in it.

Decker does not dwell on that aspect of the Dora case, but she presents an excellent description of the case itself and of the general social and cultural milieu in which all of the principal characters developed. She also makes a number of interpretive generalizations about Freud that are of questionable validity; there seems to be a growing tradition among historians and academics in other fields, such as literature, to speculate about Freud's psyche. Arlow (3) has urged us to see the case histories as "milestones on the road to great discoveries made by a genius. They are major historical documents, but they do not represent modern psychoanalytic thought and practice" (p. 21). The reader of Decker's book should certainly keep this in mind.

This trilogy, the objective of which is to demonstrate the relevance of British object relations theory to contemporary psychoanalysis, has received far less attention than it deserves. In alignment with the goals of psychoanalysis, Ogden aims to repair the effects of disrupted history. "We take for granted that one cannot understand Melanie Klein without understanding Freud," Ogden notes, but he believes that "it is also true that we cannot understand Freud without understanding Klein." A radical notion, especially since Klein has been all but ignored in the United States, but the reader of these three volumes will be hard put to disagree, even though for most of us it is unfamiliar and difficult terrain.

Klein was committed to Freud's drive theory and even held firm to the concept of the death instinct, but she brought an interpersonal frame of reference to psychoanalysis, the want of which has been a major constriction of classical psychoanalysis. There has been a recent proliferation of interest in Klein and the analysts who took her work as their point of reference and departure—Winnicott, Bion, Fairbairn, and others. Ogden summarizes, represents, and creatively extends this body of work.

There is a developmental unity to Ogden's trilogy. *Projective Identification and Psychotherapeutic Technique* describes the window through which object relations theory is linked to clinical data, which informs and is illuminated by it. In *The Matrix of the Mind* he secures the theoretical underpinning of modern object relations theory by reviewing and explicating, especially, the ideas of Klein and Winnicott. In *The Primitive Edge of Experience* Ogden adds to Klein's ideas by introducing a primitive sensory stage into the theory of early development. Throughout all of the books, he illustrates object relations theory clinically and uses it to amplify and revise classical theory.

Projective identification is that process by which one rids oneself of an unwanted mental content, like hate or a feeling of worthlessness, by projecting it into another person and then exerting powerful interactional pressure on the recipient to experience exactly what was projected. In addition to negative contents, the projected part can be something that must be placed externally for safekeeping, like hopefulness in a situation of extreme vulnerability. The therapist who is able to accept the projection and to process it in a manner differently than the patient makes the modified version available for reinternalization. Thus defined, projective identification has four components: it is a defense, a form of communication, a manner of relatedness, and, finally, a pathway for psychological change. Every occasion of transference and countertransference partakes of projective identification in some degree.

The idea that there is something therapeutic about the therapist's containment of the patient's projective identification is based on an interpersonal notion of individual psychological growth. In the range of treatment techniques these interactions richly supplement interpretation without replacing it.

An analyst became aware of feeling guilty toward his patient and recognized that he had become the repository for the patient's disowned and projected belief that he was greedy. The patient repudiated his wish to meet more frequently by devaluing the therapy and making the analyst feel he wasn't worth his fee. Thus informed, the analyst was able to "hold" feelings of appropriate self-interest, derivatives of greed, without being damaged or defensive. He didn't hide that he was glad to be paid for his work, and this made available to the patient a model of processed, detoxified self-interest on which he could begin to examine, modify, and accept those of his own needs which he experienced as greed.

In the final chapters of *Projective Identification and Psychotherapeutic Technique* Ogden theorizes about schizophrenia and arrives at the view that the central conflict in this disorder is whether to allow meanings to exist. In outlining the course of one patient's recovery he shows projective identification articulating the movement from a phase of nonexperience, in which the patient was mute, to a stage of psychotic aliveness that marked his progress into the world and on his way to a fragile form of object relatedness. During a crucial phase the therapist was able to tolerate feelings of estrangement and meaninglessness.

In *The Matrix of the Mind* Ogden speaks of different theories as different languages, each with its unique and contrasting meaning that invites new and enriched syntheses. He strongly argues the case for dialogue between theoreticians of different persuasions. Kleinian theory postulates very early fantasy activity dealing with primitive life and death forces in which the infant must separate the endangered from the endangering. This crucial task is accomplished principally by splitting. Thus, Klein believed the infant capable of well-formed mental activity in the earliest months of life, and this implausible chronology, taken literally, was the agency through which her work was dismissed. Ogden recontextualizes Klein's concepts as organizing structures, like Chomsky's linguistic deep structures—inherent readiness for highly complex and specific developments. Aside from the issue of developmental timing, Klein's two stages of early mental organization have enormous utility in clarifying the nature, development, and transition of schizoid to normal-neurotic stages. This is especially so because Klein traces relational issues in development that expand the purely intrapsychic (oral, anal, and phallic) lines of classical Freudian theory.

Klein described two stages of mental development: the paranoid-schizoid state and the depressive position. In the paranoid-schizoid state there is no central organized agency of self and the infant manages the threat of destructive fantasies by splitting off the loving and pleasureful "me" from the hateful and pain-experiencing "not-me." A primitive order reigns by maintaining discontinuities, and when this defense fails the infant suffers the experience of annihilation. Passage into the second of Klein's developmental phases is marked by an advance across the entire spectrum of mental life: enhanced capacities for differentiation, the use of symbols, modulation of affect, reality testing, and memory. It is the birth of subjective wholeness, concern for others, and the possibility of loss, thus the name "depressive position." Passage into the depressive position does not eliminate paranoid-schizoid issues, however, and a dialectical relationship continues between the two forever in which each state creates, negates, and preserves the other, permeating all future development.

In Ogden's synthesis an object relation necessarily involves a dual subdivision of the ego—a split into two new dynamic suborganizations, each with the capacity to generate meaning and experience. One part is identified with the self in the relationship and the other with the object. The beaten child might have one suborganization that is the cringing helpless child and another that is the sadistic tormenter. Each internal object relation is shaped by some specific relationship but by no means bears a one-to-one concordance with it. The internal object is an idiosyncratic construct derived from interactional reality and the experience of that reality tempered by private fantasies.

Transferences and countertransferences are always enactments of internal object relations, and they are always reinforced by projective identification. Ogden believes that it is necessary for therapists to allow themselves to experience the internal object relations of the patient in order to be able to influence the patient, a point reinforced by Winnicott's theory of the maternal holding environment. In the light of object relations theory, resistance is the difficulty a patient has in relinquishing attachments based on unconscious internal objects. Thus, object relations theory explains the commonplace that a masochistic patient who is improving so often generates a heightened sadism against the self in an attempt to restore the previous balance.

Reflections on the work of Donald Winnicott occupy the final chapters. According to Winnicott, the infant's psychological contents exist initially only within the matrix provided by the mother—a mother-infant unity. A crucial stage of development is the capacity to be alone, which follows from the child's illusion of the mother's presence during her absence and of her absence during her presence. Winnicott sees the issues of separateness very differently than do Jacobson and Mahler because Winnicott's views are rooted in interaction. In order for the externality of the mother to be discovered the child must be sufficiently secure that he can renounce her, let her go, and have her not disappear. The mother must continually provide the physical and emotional presence necessary to survive the infant's fantasied acts of destroying her.

Winnicott's concept of potential space underlies all play, imagination, dreams, and psychoanalysis. It hinges on a dialectic between fantasy and reality. The capacity for transference involves the generation of an illusion that is simultaneously real and not real, and in this "space" meanings can be created, considered, and understood. If the transference experience becomes too powerful it collapses in the direction of fantasy, resulting in a delusional transference. In defense, reality can be exalted through the excessive use of intellectualization and concrete thinking in order to foreclose dangerous imagination.

*The Primitive Edge of Experience* opens with a review of the two Kleinian modes of experience prefatory to the proposal of a third mode: the autistic-contiguous sensory "floor" of experience. "Autistic" refers to the primitive, sensory-organized, isolated self. "Contiguous" refers to the experience of surfaces touching. Once again, Ogden frames a dialectic, here between the isolated interior self and its surface, which touches other people and things. This contrasts sharply with Mahler's phase of "normal autism," which is a "monadic self-sufficient system closed into hallucinatory wish fulfillment." In Ogden's autistic-contiguous mode, objects are experienced in terms of sensory surfaces and interactions with the outside. The normal elaboration of autistic-contiguous organization makes the awareness of separateness bearable. But when the mother-infant dyad is pathologically disordered, the result in the infant is an agony of unboundedness, evoking sensations like leaking, sinking, disappearing, and falling into space.

A regressed patient's refusal to bathe was traced to dependence on his odor. Fear of showering was the terror of dissolving and literally going down the drain. Odor was the vehicle of being something and therefore existing. Ogden uses the autistic-contiguous concept to clarify aspects of the schizoid condition, where the inner world is occupied by persecutors and victims, projections of strangulated object relations cloaked in contempt and grandiosity. Ogden shows how frequently symptoms associated with schizoid conditions devolve upon repetitious sensations of smell, sound, shape, texture, and rhythm—the autistic-contiguous defenses against unboundedness.

In the final portion of this book Ogden thoughtfully plays with the ideas in the space that he has so elegantly developed in these writings. He reformulates the dynamics of entrance into the Oedipus complex, yielding clear and fresh insights; next he addresses "a collection of thoughts . . . to myself (and other novices) on the subject of the opening of the analytic drama" (the first interview); and finally he connects the fear of not knowing to the enduring effects of premature disruption of the mother-infant unity.

The central theme in Ogden's work is the issue of the dialectic. Since nothing ends and nothing passes away, all change takes place in the endless contrast of old and new mental issues that negate and affirm each other to create new levels of complexity and synthesis. "Mental contents exist in a psychological space that is at first almost entirely interpersonal, only later evolving into a personal internal environment. It is the dialectical interplay of our mental contents and the personal and interpersonal psychological space in which they are lived that constitutes the matrix of the mind."

It was a privilege to review these volumes, for they had an immediate effect on my understanding of clinical material, and it is a pleasure to recommend them to every psychodynamic clinician. It is much to be hoped that Ogden's call for dialogue between the various psychoanalytic schools becomes a dream realized. He has contributed substantively toward that end.

JUSTIN SIMON, M.D.
*Berkeley, Calif.*

**Encountering Freud: The Politics and Histories of Psychoanalysis,** *by Paul Roazen. New Brunswick, N.J., Transaction, 1990, 337 pp., $34.95.*

On completing his training in political science some 20 years ago, Paul Roazen decided to devote his career to the impact of Freud and his followers not only on politics but on the cultural and intellectual life of this century. He felt that the time had come for an objective and scholarly approach to Freud to correct the largely idolatrous (i.e., Ernest Jones) or hostile attitudes that previously had prevailed in the Freud literature. Roazen has had to traverse a rather rocky road in his endeavor. Ranged against him have been not only the somewhat bemused questionings of his colleagues but, more importantly, the opposition of the Freud establishment and the obstacles placed in the path of any nonanointed Freud researcher by the keepers of the Freud Archive and those, including the Freud family, interested more in protection than scholarship. The lack of recognition of his efforts seems to have generated some feelings of resentment in Roazen, which are evident in at least the early portions of the book under review. Thus, one can wonder whether some of his comments about Anna Freud are influenced by her judgment of him as "a rather malicious American author."

Roazen has persisted, and he has produced a creditable and interesting body of work about Freud and his influence. This includes several books, but much of his critique has been in the form of book reviews—he clearly is an omnivorous devourer and analyzer of works in his chosen and related fields—and this brings us to the current volume. *Encountering Freud* is a collection of essays devoted to different aspects of the Freudian world, largely based on reviews of books about eminent figures in the historical, literary, and political spheres as well as the psychoanalytic sphere. The number of books considered is formidable—I lost count at more than 100—and their catholicity impressive. They range—and this is just a sampling—from Adler and Rank, to Sullivan and Erikson, to Walter Lippman and Hannah Arendt, to Dostoevsky and Orwell (the discussion of the resemblances and differences between Freud and Orwell is illuminating), to Szasz and Bettelheim.

However, employing a series of book reviews as an armature for a general discussion does not produce an entirely satisfactory result. It is responsible for a certain disconcerting jumpiness and lack of cohesion. Some of the subjects considered (the insanity plea, for example) are far afield from the author's main thrust. The books dealt with were published in a period extending from the 1930s to the 1980s, and there are signs that a good deal of the material has been recycled from previous reviews. Some of the comments are now out of date. Thus, in discussing a book by Grier and Cobbs, Roazen uses "Negroes" instead of "blacks," and at another point he states that it would be unacceptable for an analyst to deal with a patient's homosexuality without trying to change it—certainly no longer true. Roazen can also be accused of some carelessness and self-indulgence, evidenced by a considerable amount of repetitiveness and by including very similar reviews of the same book about Walter Lippman in two different chapters. Roazen also assumes a degree of familiarity in his readers about the arcana of psychoanalysis and its disputes that may not be justified. This is particularly apparent in the polemical debate with K. Eissler about whether Freud should bear some responsibility for the suicide of Victor Tausk. This tempest in the psychoanalytic teapot hardly seems to justify the heat generated by it.

These strictures notwithstanding, *Encountering Freud* contains a good deal of thought-provoking material that will be stimulating to psychoanalysts, psychiatrists, academics of different persuasions, and the informed public. I believe that on the whole Roazen has been able to maintain the difficult position of participant observer of the field of applied psychoanalysis. His respect for the master's monumental achievement is evident, but, at the same time, he demythologizes Freud.

So many different subjects are treated in this somewhat overstuffed pudding of a book that an adequate summary of its main themes is not possible. One of these emphasizes the contention, certainly not a new one, that Freud's absolute domination of his followers and his intolerance of dissenters like Adler and Jung and Fromm turned these dissents, which might have been fructifying, into heresies. Roazen sees Freud and his early followers as more gifted, creative, and nonconformist than the later, prosperous members of the Freud establishment. He feels that the absence of some consensus on what constitutes normality in our society has been responsible for accusations, particularly from the political left, that the goal of psychoanalysis is a kind of success-oriented conformity, leading to strengthening of the status quo. He would like to see much more mutual respect and interaction between psychoanalysis and the social sciences and history, with the emphasis being shifted from what psychoanalysis can offer these fields to its reciprocal—what they can offer psychoanalysis.

Finally, this lively book left me with questions about the future of the immense influence exerted by Freud and Freudianism over our entire culture, which, with qualifications, Roazen celebrates. At a clinical level, questions about the therapeutic efficacy of formal psychoanalysis and the economic base underlying its practice are widespread. Although its most enduring legacy to our times, the notion of psychological factors out of awareness affecting our behavior, is secure, many other, more particular elements of Freudian theory are under challenge. The most recent evidence of this critical trend is the disillusionment expressed by Robert Holt (1) in his summing up of 30 years of attempting to rationalize both metapsychological and clinical Freudian theory. To what extent will future biographers, historians, literary critics, and political theorists continue to rely on Freudian insights as the open Sesame to understanding the mysteries of their subjects?

PAUL CHODOFF, M.D.
*Washington, D.C.*

**New Perspectives on Narcissism,** *edited by Eric M. Plakun, M.D. Washington D.C., American Psychiatric Press, 1990, 252 pp., $28.50.*

This book consists of a collection of articles ranging from a history of psychoanalytic conceptualizations of narcissism, through epidemiologic and empirical statistical studies, and ending with four case presentations by the editor subsequently discussed by Otto Kernberg and Paul Ornstein according to their respective points of view. The stated purpose of the book is "bridging the gulf between psychoanalytic conceptualizations and empirical psychiatry, with those interested in each subject finding something of value, but also an opportunity to learn something from the other's point of view" (p. xiv). All of the six articles in the book are written by professionals who are respectable within their chosen disciplines.

Such a book requires an astute editor with a careful eye on the needs of whoever is to be its intended audience. The assumption must be that the expert epidemiologist will not be sophisticated about psychoanalytic conceptions, the psychoanalyst will not know much about empirical research and statistics, the psychiatrist may not be an expert in any of these areas, and the resident or mental health trainee will need special explanations or attention. At the very least, therefore, such a book should have an index and a summary in simple language of the chapter's main points at the end of each chapter. This book has neither of these vital features. The brief orienting statement by the editor before each chapter does not suffice. In addition, it would have helped to put all the references in one place at the end of the book instead of after each chapter, in order to make them easier to find. Most important, each of the four case histories should have been immediately followed by Kernberg's and then Ornstein's discussions rather than presenting all the cases in one chapter and having Kernberg and then Ornstein both go over all four in their subsequent chapters. The present organization forces the reader to thumb back and forth over and over to follow the discussants against the case histories and to compare them with each other. The title of the book, *New Perspectives on Narcissism,* is misleading because it presents nothing new, only a review of relatively recent concepts and selected points of view. As such, the primary audience should be those who wish to keep up with certain developments over the past decade or two, but not readers who are looking for new ideas or discoveries.

Plakun tells us that his book is to be a "compendium of the leading psychoanalytic conceptualizations of narcissistic personality disorder, with special emphasis on its relationship to borderline personality disorder" (p. xiv), but those who are interested in such psychoanalytic perspectives would do better to read the outstanding work by Abend et al. (1), noting especially their discussion of narcissism on pages 180–184. The opening chapter in the book under review, by James Sackstededer, M.D. (who is not identified as a psychoanalyst), is overly ambitious and tries to include not only psychoanalytic conceptualizations of narcissism but summaries of entire bodies of psychoanalytic theory, which makes for very difficult reading indeed. The editor should have suggested to Dr. Sackstededer that he not include long complex quotations from difficult writers such as Edith Jacobson in the few pages devoted to each theorist. Rather, he could have paraphrased their work in language that less sophisticated readers could understand and confined his review more strictly to concepts of narcissism. There is nothing seriously flawed in what he says, but the style and organization should have been corrected.

The next two chapters, involving epidemiologic data and empirical research data, are reports of preliminary research on small and select groups, and only someone sophisticated in psychiatric research could appreciate and evaluate them.

The last 100 pages comprise the final three chapters presenting the four cases and then discussions of the cases by Kernberg and Ornstein. I was puzzled to find Kernberg's view labeled an "ego psychology–object-relations perspective," which would perhaps mislead the unsophisticated reader into thinking that Kernberg's views are the same as those of Heinze Hartmann's school; they are not. No representative of current traditional ego psychology and psychoanalysis is included in the book, nor is the recent work by Rothstein (2) or the continuing contributions by Masterson and many others. Kernberg is refreshingly honest when he states that the data supplied in the case presentations "preclude anything except speculations" (p. 202). Ornstein more gently recognizes the same limitations but fleshes out his chapter with some review of self psychology.

So, although there is little to oppose in the actual content of the book, I cannot imagine what reader would be willing to plow through it or even be qualified to do so. Psychiatrists interested in Kernberg's point of view or in Ornstein's approach might enjoy their respective chapters, but these authors have developed their theories and approaches at length and using much better case material in many other publications.

**The Psychoanalytic Core: Essays in Honor of Leo Rangell, M.D.,** *edited by Harold P. Blum, M.D., Edward M. Weinshel, M.D., and F. Robert Rodman, M.D. Madison, Conn., International Universities Press, 1989, 519 pp., $60.00.*

This Festschrift, honoring the many contributions of Leo Rangell, M.D., over a professional lifetime of exciting and consistent high-quality teaching, writing, thinking, treating, and administrative activities, celebrates his 75th birthday. His close friends and colleagues have contributed 25 chapters to this collection of essays. The authors address several topics that relate to their own current work as well as to the earlier contributions of Leo Rangell. Although Rangell's research has focused on the more classic psychoanalytic theoretical and technical approaches, he has, as Blum notes in his dedicatory essay, "also enlarged our vision of group process, political process, and social regulation" (p. 1). In the last chapter of this volume there is a listing of Rangell's publications arranged chronologically from 1942 to the present. In reading these one can follow his development from neurological studies to psychoanalytic contributions.

Rangell has devoted many years to psychoanalytic administrative activities. He was President of the American Psychoanalytic Association twice, President of the International Psycho-Analytical Association twice, and served as President of the Los Angeles Psychoanalytic Society for three terms. Blum's introduction yields biographical data on Rangell's life, accomplishments, awards, and prizes. Arlow's brief personal memoir of Rangell and Rodman's elaboration of the theoretical and clinical contributions of Rangell complete this introductory section.

In the following chapters we find a diversity of topics addressed by leaders in psychoanalysis, such as Weinshel on inconsolability, Brenner on dreams and symptoms, Harley on the primal scene, and Wallerstein on psychoanalysis and psychotherapy. It is not space effective to list all of the other authors and their very stimulating topics. These contributions include essays by colleagues from England, France, Israel, Spain, Holland, and the United States. Many of the authors are basically oriented to ego psychology. The papers themselves are clear, well written, clinical, and theoretical, and they give the reader an excellent overview of current psychoanalytic contributions. There are papers, for example, on developmental psychoanalysis, ethics, psychoanalytic organizations, and holocaust studies.

This is a fitting tribute to a devoted, hard-working, pioneering psychoanalytic teacher. I am certain that he is proud and pleased by the tribute paid him by his friends and esteemed colleagues. For those of us who wish to see what some of our leading colleagues are working on, this volume, although not saying it all, says so much that it can and should be read by psychoanalysts the world over. The editors are to be congratulated for bringing us closer to one of the pivotal current psychoanalytic cores.

GEORGE H. POLLOCK, M.D., PH.D.

## FORENSIC PSYCHIATRY

**American Psychiatric Press Review of Clinical Psychiatry and the Law, vol. 1,** *edited by Robert I. Simon, M.D. Washington, D.C., American Psychiatric Press, 1989, 373 pp., $38.50.*

In the preface to this volume, the editor recalls that capable psychiatrists at a hospital where he attended grand rounds panicked after being sued for the first time. Some of the attending staff "darkly hinted at early retirement." With the well-known increase in psychiatric malpractice litigation in recent years, fear and defensive psychiatry have begun to jeopardize self-confidence and sound clinical practice. The increase in litigation is paralleled by greater legislative and judicial regulation of the profession. Ethical guidelines promulgated by APA and other professional organizations interface with legislative statutes and judicial decisions in complex and sometimes conflicting ways. In this atmosphere of anxiety and confusion, the clinician would do well to learn more about his or her ethical and legal responsibilities. The reviews in this volume are a good place to start. The authors are experienced clinicians who provide practical advice on how to avoid legal entanglements, but, more importantly, they keep in mind the broader question of how to do so while promoting the best possible patient care. They educate about clinical practice while informing about the law.

Volume 1 is divided into four sections, each with its own editor, covering Somatic Therapies and the Law, Confidentiality in Psychiatric Clinical Practice, The Duty to Warn, and Psychiatric Legal Diagnostic Dilemmas. Three feature articles follow, in which recent legal decisions are summarized, a hypothetical case of negligent care of a suicidal patient is presented with arguments from both sides, and instructions are given on how psychiatrists should conduct themselves in the courtroom. The hypothetical case and arguments that follow are particularly well written and elucidate many of the ethical and legal dilemmas discussed in the rest of the book. However, a case directly related to the topics of the previous sections would have been more suitable.

In his section on somatic therapies, Simon adheres firmly to the idea that the best way to avoid lawsuits is to practice good clinical care with a knowledge of the law at hand. He clearly maps out areas of pretreatment and posttreatment liability, advising us to protect ourselves through adequate assessment of the patient, proper attention to diagnosis, informed consent, record keeping, and careful ongoing risk/benefit analysis. The all-important issue of standard of care is well covered, with cases to illustrate court rulings on this matter. In most instances, psychiatrists are free to exercise their best clinical judgment, as long as they have professional guidelines, accepted practice, or clinical studies to back them up. Defensive psychiatry can be bad psychiatry and so make us more vulnerable to lawsuits. This section contains a good discussion of treatment dilemmas posed by tardive dyskinesia, with practical guidelines for avoiding liability. Overall, Dr. Simon does a good job of guiding us between the Scylla and Charybdis of careless treatment and unwarranted defensiveness.

Confidentiality and privilege are areas in which the legislature and courts have become increasingly more involved. The authors of this section review the historical, ethical, and legal aspects of these concepts and the limits of both with an eye toward identifying areas of competing duties. Should one release information to an employer or insurance company that may be damaging to the patient and ultimately compromise the therapeutic alliance? Here the economic realities of modern society, readily apparent to the courts, may infringe on less comprehensible processes that take place in the privacy of the office. The authors do not dodge these issues but attempt to identify them, to clarify the ethical and legal dilemmas involved, and to call for changes when they recognize conflicts between patient care and unreasonable legal requirements.

They provide assistance in charting the best course through difficult decisions, again with optimal patient care foremost in mind. Issues of confidentiality in the era of AIDS, in disputes over child custody and visitation, and with children and adolescents are covered in separate chapters with plentiful reference to legislative statutes, case law, and ethical codes.

The topic of the duty to warn logically follows confidentiality because these are two potentially conflicting duties the clinician may face in practice. The five chapters in this section range in coverage from the moral and political underpinnings of the duty to warn (more properly the duty to protect) through practical issues of how to manage potentially violent patients, including those behind the wheel of a car. Drs. John W. Douard and William J. Winslade argue that the conflict between confidentiality and the duty to protect is rooted in the moral imperative to protect those who are vulnerable and dependent. This includes third parties as well as the patient. Both are entitled to equal concern and respect derived from the right to equality. Problems arise when the courts, in the absence of legislation, must decide to what extent third parties include those not specifically named by the patient. Are we as therapists responsible for protecting all of society at large? The trend has been to increase our responsibility to third parties while concurrently protecting the civil rights of the patient with regard to involuntary commitment. This results in the clinician's increased vulnerability because more weight is placed on the proper exercise of due care. The situation is exacerbated by the fact that the extent of the clinician's duty to protect is often unlegislated and, therefore, subject to variable court decisions. Whether or not one agrees with Drs. Douard and Winslade that greater legislative action is needed, it is clear that the clinician is now more vulnerable and needs to weigh conflicting duties carefully.

Dr. James C. Beck, in his chapter on the clinical aspects of the duty to protect, provides valuable insights into the practical aspects of assessing and managing potentially violent patients and handling conflicting duties. The *Tarasoff* principle is really a duty to protect in which warning a third party is only one way of discharging that responsibility. Dr. Beck shows how to preserve the therapeutic alliance by matching alternatives to the level of concern for violence. In the end, a violent patient may be relieved by the clinician's exercise of restraint, even if this means warning a third party or hospitalizing the patient involuntarily. The important thing is how one conducts oneself with the patient. Dr. Beck's discussion, based on his own experience and using clinical examples, is very helpful in reconciling our concern for the patient with our responsibilities to society.

In the last section of these reviews, Dr. Harold M. Ginzburg discusses the concepts of negligence, dangerousness, the duty to protect, and emotional harm from the point of view of the evolution of legal theory and its relation to psychiatric knowledge. Some of the same ground covered in previous reviews is covered here, but in more detail and with greater emphasis on court decisions that have influenced these concepts. Dr. Ginzburg points out that "dangerousness" is not a *DSM-III-R* diagnosis, yet according to the California Supreme Court majority rule on the *Tarasoff* case, therapists in their capacity as professionals are virtually expected to predict dangerousness. Studies have shown that therapists are not able to predict dangerousness with any certainty; therefore, these court decisions are not congruent with our knowledge about what psychiatrists are able to do. Dr. Ginzburg shows how dissenting opinions in California, Colorado, and elsewhere make the duty to protect still a much debated concept. Although aspects of the duty to protect may be at odds with psychiatry, the legal concept of emotional harm has evolved in ways consistent with psychiatric knowledge. We know that psychological trauma can result from experiences other than physical harm, and the courts have reflected this in their decisions about what constitutes emotional harm. This section is interesting for its legal theory but would have been enhanced by greater discussion of psychological concepts and an attempt to find solutions to these psychiatric-legal dilemmas.

This collection of reviews goes far toward introducing the clinician to the interaction between psychiatry and the law. The topics range from fundamental moral issues to very practical problems of patient management. Throughout, the focus is on facilitating good clinical care rather than on just avoiding lawsuits. Although this book abounds with citations of ethical codes, legislative statutes, and case law, readers quickly realize that they must get to know the ethical codes in full and the statutes in their own states. In addition, one must have adequate malpractice insurance, and a more than passing familiarity with a forensic psychiatrist may prove helpful. Readers of this book will be more knowledgeable about conflicts of duty and better prepared to handle them. The waters may be rough, but there is no need to jump ship.

## Cognitive Impairment in Dramatic Personality Disorders

SIR: Several recent articles have demonstrated neurocognitive impairment in subjects with borderline and other dramatic personality disorders (1–3) despite long-standing empirical evidence that cognition in persons with personality disorders falls within population norms (4). Several hypotheses attempt to explain why cognitive impairment has not been demonstrated by normative comparisons: 1) past studies may have used the wrong cognitive measures (e.g., failed to use tests of prefrontal functions) (1); 2) the effect can only be demonstrated in selected test populations (e.g., markedly impaired patients or high-performing control subjects); 3) the effect is highly variable and/or not normally distributed across patients and test measures; or 4) the effect is either very slight or spurious.

We tested these hypotheses by administering neurocognitive screening tests to a group of patients with personality disorders. The subjects were 25 male patients, mean±SD age=37.2±5.5 years, in a milieu therapy program at a Veterans Administration hospital. All had diagnoses of mixed personality disorders within the dramatic cluster (*DSM-III-R* cluster B), with borderline and antisocial disorders predominating. The subjects had past histories of substance abuse, but continuing abstinence was confirmed by taking random weekly observed urine samples. Only three individuals had lifetime histories of head trauma sufficiently severe that they had sought medical care. The group was high functioning to the extent that members successfully negotiated cognitively and emotionally demanding milieu rules and activities; many held part-time jobs in the community during the day.

Neurocognitive tests (5) included the Benton Figure Drawing Test (Form 1, Administration C, norm ≥6/8), the Reitan Trails B test (norm ≤99 seconds), the WAIS Digit Symbol test (norm ≥34), the difference between verbal and nonverbal IQs on the Hartford-Shipley test (norm ≤20), and a Luria repetitive figure drawing task (norm ≥6/7). The number of patients with scores below these norms was compared to the expected distributions by means of chi-square tests.

The results showed 32% of the patients scoring below norms on the Trails B test ($\chi^2$=11.77, df=1, p=0.001), 25% with verbal IQ greater than nonverbal IQ by 20 or more points ($\chi^2$=6.32, df=1, p=0.01), and 16% below norms on the Benton test ($\chi^2$=4.76, df=1, p=0.03). Twelve percent of the patients were below norms on the WAIS Digit Symbol test, and 10% were below norms on the Luria repetitive drawing test; these differences were not significant.

These results demonstrate that a high proportion of patients with dramatic personality disorders may show neurocognitive deficits when their test scores are compared with general norms. These neurocognitive tests are sensitive to brain dysfunction across many brain loci, but they are not specific for impairment in any brain area(s) (5). Their ease of administration should enable other researchers to test these findings and/or assess the clinical importance of neurocognitive impairment in their own patients. Patients who show deficits on general cognitive screening tests could then be given a comprehensive workup, which could point to any focal areas of cognitive dysfunction (1).

Our results support hypothesis 3: that cognitive impairment is quite variable across patients and between different test measures. The sources of this variability and its meaning for theories of personality disorders are yet to be determined. Cognitive dysfunction may have implications for both our understanding and our treatment of patients with personality disorders (1–3).

## Ineffectiveness of Clomipramine for Obsessive-Compulsive Symptoms in a Patient With Schizophrenia

SIR: Although the relation between obsessive-compulsive disorder and schizophrenia has been debated for decades (1), obsessions and compulsions do occur in a considerable number of persons with schizophrenia. Treatment has not helped (1), and outcome has been poor in some series of patients (2). There have been a few reports (3–5) of the use of clomipramine for obsessive-compulsive symptoms in schizophrenia that suggested improvement in a majority of the patients treated. However, some patients became more psychotic. With the recent general availability of clomipramine, this drug will surely be increasingly tried in schizophrenic patients with obsessive-compulsive features. Clinicians should be aware of the potential for some of these patients to worsen when treated with clomipramine. We report such a response in a patient with chronic schizophrenia and marked ritualistic compulsions.

> Mr. A was a 33-year-old man with chronic undifferentiated schizophrenia who had been in the hospital 8 years and had had seven previous hospitalizations in as many years. He exhibited a wide variety of bizarre and persecutory delusions, auditory hallucinations, and aggressiveness controlled but not eliminated by antipsychotic medication. He also showed poor concentration, poor self-care, restless-

ness, intrusiveness, and episodic excessive water drinking, but he was generally friendly and cheerful. In addition, he had repetitive stereotypical behaviors with an evident compulsive quality. For example, he would stand in the hall or day room, repeatedly taking his shoes off and putting them on and lacing them up, with periodic pauses. He would not move until he had finished, even during ward meetings. Similarly, he would put his shirt on and take it off, button and unbutton his pants, and touch walls, doors, and garbage cans in a compulsive manner. When asked why he engaged in these ritualistic behaviors, he generally had no explanation. These symptoms had not responded at all to treatment with numerous antipsychotics including clozapine. There was no sign of organicity on mental status, neurological, and CT scan examinations.

Mr. A had previously shown no response and some increased agitation, hostility, insomnia, and paranoid ideation when taking fluoxetine, 60 mg/day, added to thiothixene. A regimen of clomipramine, 25 mg/day, was started and slowly increased over 10 weeks to 250 mg/day, while he continued to take mesoridazine, 300 mg/day. No change in his compulsions was observed during this time, but between weeks 2 and 6 he was reported to be more hostile, paranoid, and angry. The dose of mesoridazine was increased to 400 mg/day, and there was temporary improvement. Two weeks after his dose of clomipramine had reached 250 mg/day, he was again suspicious and hostile, abusive, aggressive, and more deluded. The mesoridazine was stopped, and perphenazine was started and increased to 64 mg/day. Two weeks later, clonazepam was added and increased to 6 mg/day, which calmed him and controlled his aggressiveness. He continued to take 250 mg/day of clomipramine for 8 weeks, with no change in his compulsive behavior. After the clomipramine was reduced and stopped, the clonazepam was also reduced and stopped without recurrence of the hostility and aggressiveness.

In this case clomipramine caused a slight worsening of the psychosis and agitation, with no effect on the obsessive-compulsive symptoms. Clomipramine is a relatively selective serotonin reuptake inhibitor and has been found to be helpful in obsessive-compulsive disorder, suggesting a central serotonergic dysfunction in patients with this disorder. The lack of effectiveness of serotonin-enhancing strategies in this patient with schizophrenia and obsessive-compulsive rituals argues against a serotonergic dysfunction mediating his obsessive-compulsive symptoms.

## Oral Caffeine Augmentation of ECT

Sir: For geriatric major depression, ECT is one of the most effective and safe treatments available. However, the practice of ECT continues to be refined in order to improve further its efficacy and side effect profile.

One area of research is the factors affecting seizure threshold; seizure threshold increases with age and during a course of ECT (1). These factors are important in the treatment of elderly patients. Missed or inadequate seizures may preclude a response in patients for whom ECT is the last viable treatment option. If bilateral ECT is used, acute cognitive side effects may result.

Intravenous caffeine will extend seizure duration during ECT without causing anxiety or affecting hemodynamics associated with ECT (2–4). Intravenous caffeine sodium benzoate is not available in Canada, and there are no published reports on the use of oral caffeine augmentation. We have been prescribing oral caffeine and successfully lengthening seizures that had previously fallen below 25 seconds in duration. For more than 30 depressed geriatric patients, we have used 100-mg caffeine tablets dissolved in 5 ml of water, administered 1 hour before treatment. We titrated the dose (300–1000 mg per treatment) according to response. The higher dose was usually required later in treatment.

Our geriatric patients did not experience any additional complications when caffeine was added to their ECT regimen. We found no evidence of peri-ECT complaints of anxiety or dysphoria and no serious cardiovascular, hemodynamic, or anesthetic complications.

While none of our patients who received the caffeine augmentation displayed abnormally prolonged seizures or dramatic cognitive deficits, there are reports suggesting that post-ECT delirium and memory loss may be associated not only with stimulus intensity but also with seizure duration (5). Therefore, the potential benefits of oral caffeine may be diminished if seizure duration becomes excessive. However, it has been our experience that oral caffeine augmentation will decrease the frequency of missed or inadequate seizures without an increase in adverse effects, thus minimizing the need for higher stimulus dosing and a protracted course of treatment.

Further work needs to be done to determine whether caffeine-augmented ECT would not only convert failed seizures but also allow for successful unilateral ECT in cases in which bilateral treatment had been previously used.

## Pharmacotherapy and Psychotherapy for Major Depression in a Man With AIDS

SIR: There have been relatively few reports of the treatment of depression coexisting with AIDS (1, 2). We report the success of combined pharmacologic and psychotherapeutic treatment of major depression in a man with AIDS.

> Mr. A, a 38-year-old man in a long-standing homosexual relationship, was admitted to a psychiatric unit with a 6-month history of major depression (nonpsychotic, single episode). Results of cognitive testing, physical examination, RPR, thyroid studies, and EEG were all normal. His symptoms included profound and unremitting dysphoria, passive suicidal ideation, hypersomnia, poor concentration, indecisiveness, and decreased libido, interest, and appetite. His Beck Depression Inventory score was 34, indicating severe depression. Although his illness was stable at admission, he had developed AIDS almost 4 years earlier, with the diagnosis of Pneumocystis carinii pneumonia. Complications included two further bouts of this pneumonia and cytomegalovirus retinitis.
>
> Nortriptyline was started and the dose adjusted to a serum level of about 100 ng/ml. After 2 weeks, Mr. A's depressive symptoms had diminished considerably and he was discharged. He elected to begin weekly psychotherapy, which centered on a "being-with" contact (3) involving an active and supportive approach as a means to bolster appropriate defenses and to broach issues about his illness. Subthreshold depressive symptoms gradually diminished and were absent 3 months after discharge. Mr. A completed a will and resumed contact with estranged relatives. His relationships improved markedly, and he noted profound satisfaction from his social contacts. Concurrently, his medical status worsened: he developed monocular blindness from a vitreous hemorrhage, pulmonary "atypical" tuberculosis, severe fatigue, and pancreatic insufficiency. His Beck depression score 7 months after admission was 13, entirely attributable to physical symptoms. He died of an undiagnosed pneumonia 9 months after admission.
>
> Because Mr. A was followed in the Multicenter AIDS Cohort Study (4), additional data were available. Magnetic resonance imaging scans of his brain 4 months before and 7 months after admission showed marked volume loss. Serial neuropsychiatric testing did not document appreciable cognitive decline.

This patient evidenced an excellent response to pharmacotherapy and supportive psychotherapy despite significant physical deterioration. While some degree of "depression" is expected with a terminal disease (5), his condition deviated from this considerably; rather than being preparatory, his depression markedly interfered with the process of dying. If his case can be generalized to those of others with AIDS, treating major depression can yield substantial benefit.

## Seizure With Low Doses of Clozapine

SIR: We were interested in reading "Clozapine and Seizures" by Ellen Haller, M.D., and Renée L. Binder, M.D. (1), who proposed useful clinical guidelines for managing the risk of seizure with clozapine treatment, which seems to be higher than with other antipsychotic drugs, according to a dose-dependent relationship.

The authors reported four cases and mentioned two previously published cases (2) of seizures with clozapine. Among six patients, only one received low doses of clozapine (75 mg/day), but that patient had a preexisting seizure disorder. High doses (more than 600 mg/day), rapid dose increases, polypharmacy, and organic pathology were mentioned as risk factors for seizures with clozapine.

We report the case of a patient with none of these risk factors who developed convulsions while taking clozapine.

> Mr. A was a 30-year-old man with a 2-year history of paranoid schizophrenia, which had been resistant to haloperidol, 20 mg/day. Neither seizures nor substance abuse was mentioned in his past history. He was placed on a regimen of clozapine therapy alone, after haloperidol had been stopped for a week. Results of a pretreatment physical examination, laboratory tests, and an EEG were within normal limits. The initial dose of clozapine was 25 mg/day, with a 25-mg increase every 2 days. When receiving 150 mg/day, on the 13th day, Mr. A had a generalized grand mal seizure that was witnessed by ward staff members. An EEG made 2 days after the seizure showed bilateral ictal activity with spikes over basal areas. Clozapine was then immediately stopped, and electrical disturbances slowly lessened in 10 days, as shown by repeated EEGs.
>
> The findings of a CT scan were normal, and other possible causes were eliminated. The patient refused to continue to take clozapine, even with anticonvulsive treatment. He was later given pipotiazine, 60 mg/day, and his EEG remained within normal limits after 8 weeks of treatment, but psychiatric improvement was still minimal.

This report is consistent with the conclusions of Dr. Haller and Dr. Binder, suggesting that clozapine treatment necessitates particular care with respect to seizure risk. Our patient had a convulsion at the very beginning of treatment, with low doses; the dose increase was prudent; he was taking no other drug; and he showed no clinical or EEG ictal activity with either haloperidol or pipotiazine.

In addition to the recommendations of Drs. Haller and Binder, we propose keeping a close watch over EEGs at the beginning of treatment, during increases in dosage, until a maintenance dose is reached. Such supervision may be useful in detecting electrical but subclinical ictal activity, which would imply slow increases in dosage. Further observations will be necessary to determine whether these precautions are valid for avoiding seizures with clozapine.

### Flunarizine as Maintenance Treatment of a Patient With Bipolar Disorder

SIR: The efficacy of lithium in the long-term treatment of bipolar disorder is well documented (1). However, there are patients who experience severe side effects from lithium. For them we must have an alternative. The efficacy of calcium channel blockers in the treatment of affective disorder has been demonstrated in several studies (2–4). Verapamil has been used in acute manic episodes as well as in maintenance treatment. There are also isolated reports of the use of other calcium antagonists in treating affective disorders, but none involving long-term treatment (3).

We report on a patient with bipolar disorder (*DSM-III-R*) who has been treated for more than 3 years with flunarizine (Sibelium; Janssen Pharmaceutica, Piscataway, N.J.). Flunarizine, a selective calcium-entry blocker, is used for several conditions, including migraine, and the recommended dose is two 5-mg tablets once daily, which is also the dose used by our patient.

Ms. A, 36 years old, has a family history of affective disorder. Since her first attack at the age of 17, she has had more than 20 episodes of affective illness. Since the age of 19 and up to the time when she was given flunarizine, she had been hospitalized 15 times for manic and depressive episodes, mainly for mania. Despite therapeutic plasma levels of lithium, the attacks remained severe and necessitated the use of high doses of neuroleptic agents. She was also given ECT and showed clear improvement. Her long-standing lithium-induced hypothyroidism was treated with L-thyroxine sodium. Severe adverse reactions—diarrhea, acne, and severe tremor—necessitated discontinuation of lithium. She was considered free of detectable organic disease and without contraindications for treatment with flunarizine. Flunarizine was substituted for lithium without a washout period.

The diarrhea ended in a few days, and Ms. A was free from acne within a month. Her mental health improved as the side effects disappeared. She has been working and functioning well. Routine medical checkups, including hematological and biochemical assessments, have been carried out regularly without any abnormal findings. The drug has been well tolerated, and no side effects have been encountered. Steady-state plasma levels have varied between 34 and 91 ng/ml. After nearly 3 years of maintenance treatment with flunarizine, Ms. A developed a moderate depression in connection with a stressful life event. At her own request ECT was used, and she clearly improved. There was no need to discontinue the flunarizine treatment.

Flunarizine may be effective as an alternative to lithium for patients who are unable to tolerate lithium's side effects. The limitations of an isolated case report, however, are obvious, and no firm conclusion can be drawn from it, although the treatment period in this case has been long. The patient has also been euthymic for a longer period of time than when she was taking lithium. It seems likely that the brief depressive attack was brought about by the stressful event rather than being drug-related. However, there is a need for well-designed longitudinal studies to evaluate the potential efficacy of flunarizine as a prophylactic treatment for bipolar disorder. Such a study is planned.

### Methadone Treatment of Tourette's Disorder

SIR: The following case illustrates the use of methadone in the treatment of Tourette's disorder.

Mr. A, a 43-year-old man, had suffered from various tics since the age of 12, except for 2 months during his 21st year and a few shorter periods afterward. His motor tics consisted of repeated eye blinking, dangerous motions with objects (cigarettes, knives, and the like), sudden jumping up, copropraxia, etc. His vocal tics consisted of coprolalia, echolalia, and palilalia. Moreover, Mr. A suffered from inner tension, obsessive and self-mutilating thoughts, compulsive acts, and sleep disturbances. In recent years, lithium carbonate and lormetazepam had been prescribed because of manic episodes. In 1989 Mr. A was admitted to our psychiatric hospital because of alcohol abuse. His consumption of alcohol had increased after the tics increased. In the past he had been treated with a variety of medications: zuclopenthixol, fluphenazine, thioridazine, haloperidol, pimozide, clonidine, and a combination of sulpiride and verapamil. Akathisia occurred with each drug, and there was only a doubtful effect on the tics. Cannabis, tried once, had no effect on the tics and worsened the inner tension. Alcohol also did not influence the tics, although they were experienced as less irritating.

After a medical staff meeting in which there was discussion of the case of a man suffering from Tourette's disorder whose tics disappeared when he used heroin and, later on, methadone (1), it was decided to try methadone for Mr. A. He promised to stop alcohol abuse, and a contract was made in which both the patient and the therapists had the right to stop the methadone treatment. The treatment started at 30 mg/day of methadone, and the dose was raised in regular increments over 26 weeks to 110 mg/day. Gradually, the tics diminished in number and intensity. Mr. A also succeeded in postponing them during conversation, bus travel, etc. He resumed riding a bicycle and handled sharp objects without difficulties. To evaluate the effect of the drug several times under identical circumstances, we counted tics during five different administrations of the Rivermeet Behavioural Memory Test. The number of tics was reduced to one-quarter, from 72 tics per 20 minutes without methadone to 18 and 19 tics at doses of 90 and 105 mg/day of methadone, respectively. Mr. A's scores on the Hamilton Rating Scale for Depression gradually decreased from 13 without methadone to 2 at a dose of 105 mg/day. When he first started methadone, there were temporary side effects: nausea, itching, and hesitation on micturition. Moderate chronic constipation and some languor in the early morning remained permanently.

After 56 weeks of continuous treatment, Mr. A is still using 110 mg/day of methadone. We cannot establish that he has developed tolerance to the drug. When we again counted tics under the standard circumstances, there were 23 tics in 20 minutes, and again the depression scale score was 2. There is no longer alcohol abuse. Our impression is that methadone treatment is successful in this patient with Tourette's disorder.

### Situational Influence on Development of Delusions of Pregnancy in a Man

SIR: We read with interest the letter of Georges Bitton, M.D., and associates (1) about delusions of pregnancy in a man. The authors made the point that such delusions have usually been reported in men with organic brain damage but that their case illustrated a similar phenomenon in the absence of identifiable cerebral pathology. We would like to extend their observations further with a case illustrating a strong situational influence on the development of delusions of pregnancy in a man.

Mr. A, a 34-year-old divorced, bisexual man, was admitted to a general psychiatric unit with an episode of mania with psychotic features. His diagnoses were bipolar mood disorder and alcohol abuse. The latter was not prominent at the time of admission and had caused no identifiable permanent cerebral damage. Results of a neurologic examination were within normal limits, and there was no evidence of cognitive impairment on mental status examination. HIV test results were negative.

The psychotic symptoms initially consisted of persecutory delusions quite similar to those the patient had experienced during previous manic episodes. However, the unit to which he had been admitted during this and prior episodes had recently developed a subspecialty program for the care of pregnant mentally ill women. Pregnant women in their third trimester occupied four of the unit's 18 beds and received specialized treatment, including group treatment, nutritional supplementation, and educational programs geared to their needs (2). Mr. A began to spend a great deal of time with these women. He then began to order double meals and drink all of the milk supply for the pregnant women. He gained considerable weight and began wearing large, loose-fitting clothes. When questioned about this behavior, he asserted that he too was pregnant. He would pat his abdomen and say, "I don't feel the baby moving" and "I shouldn't be smoking these cigarettes; they're bad for the baby." He questioned female nursing staff members about how labor had been for them, so that he would know what to expect. He had two daughters whom he had missed greatly since his divorce, and he now spoke of how he would have another one. He wanted very much to join the unit's groups for pregnant patients.

As his mania cleared, the patient recognized these ideas as delusional and spoke in a rational way about wishing he could be a better father to his daughters. Although his longing for his daughters had been a chronic concern, delusions of pregnancy had never appeared before and did not recur in a subsequent episode.

Although the numbers are too small for statistical corroboration, it is the impression of the staff on this unit that since the introduction of a subgroup of visibly pregnant patients who receive special treatment, there has been a notable increase in delusions of pregnancy among other patients who are not pregnant or delusions that a significant other is pregnant. Contextual variables may exert a strong influence on the content of such delusions, particularly in cultures or settings in which pregnancy confers a highly valued social status.

### Differentiating Paranoia and Legitimate Fears

SIR: I was interested to read about the "paranoid" patient who really was being chased by the Mafia and police (1). That account reminded me of the following case.

Mr. A came to the emergency department of a psychiatric hospital in Canada and requested a supply of thiothixene. He stated that he was a U.S. citizen and had been receiving treatment for schizophrenia in several U.S. hospitals for a number of years. He claimed that some years earlier, while he was watching a news broadcast on television, he had made an idle remark about Presidential assassination. His comment was reported to authorities, he was convicted of threatening the life of the President, and he served a sentence in a federal prison. He received psychiatric care while serving the sentence.

Mr. A claimed that after his release he was followed everywhere by Secret Service agents, and as a result of their harassment he was unable to hold down jobs or find a permanent residence anywhere in the United States. In desperation he had come to Canada, hoping that Canada would provide refuge from the persecution he felt in the United States. He expected to begin a new life here. Although Mr. A exhibited no signs of mental disorder, his statements about receiving treatment for schizophrenia sounded plausible, and his comments about Secret Service agents seemed consistent with that diagnosis. He was given a small supply of thiothixene and an appointment to return in 2 weeks' time.

Six days later Mr. A reappeared in the emergency department. He was very distraught. He claimed that Secret Service men had located him and were following him on the street and that one agent had snapped a picture of him from behind a parked car. He felt that it was pointless to pursue his goals in Canada, and in his disheartened mood he considered drowning himself. He was easily persuaded to be admitted to a hospital, feeling he would be protected from harm and helped to resolve his problems with U.S. government authorities. The admitting diagnosis was acute situational maladjustment associated with paranoid schizophrenia.

Soon after Mr. A's admission, the hospital received a call from a Canadian immigration official. He identified Mr. A by name and inquired whether he was receiving psychiatric care. He indicated that U.S. government agents were interested in Mr. A's whereabouts. After some discussion, Mr. A agreed to meet with Canadian officials to discuss his eligibility for political asylum in this country. He felt optimistic about this turn of events and requested discharge from the hospital. He made no further contact with the hospital after his departure.

The U.S. Secret Service keeps permanent files on individuals who have made threats against the President. These individuals are subject to frequent monitoring and security evaluations by agents within and outside the United States (2). Like Mr. A, many patients who have been identified as potential threats to the President or other White House figures are white, unmarried men suffering from paranoid schizophrenia (3). His account of persecution by undercover government agents, like the tale of persecution by New York Mafiosi and police told by the patient in the case reported by David Mayerhoff, M.D. and associates (1), sounded implausible and pathological. As Dr. Mayerhoff and colleagues reminded us, sometimes "paranoid" people have real persecutors.

### Relation of Age to Prevalence of Tardive Dyskinesia

SIR: Vikram Khot, M.D., and Richard Jed Wyatt, M.D. (1) reported a meta-analysis of nine studies to provide age-specific estimates of the prevalence of neuroleptic-associated dyskinesia (more than 3 months' exposure to neuroleptics) and spontaneous dyskinesia (less than 3 months' exposure to neuroleptics). Both of these conditions were reported to increase sharply in prevalence from age 16 to 59 years, followed in later years (up to age 89) by a plateau or modest decline in their prevalence rates. Age-specific rates of true tardive dyskinesia were calculated by subtracting age-specific rates of spontaneous dyskinesia from corresponding rates of neuroleptic-associated dyskinesia. The authors found that "the true prevalence of tardive dyskinesia changes relatively little with increasing age."

We rated the presence and severity of dyskinetic movements for 45 elderly patients (mean±SD age=72.4±8.1 years, range=60–91) who were admitted for acute inpatient care to the geriatric clinical research unit at our facility (2). Cases of dyskinesia required a rating on the Abnormal Involuntary Movement Scale of mild in at least two body areas or moderate in at least one body area. Only seven (16%) of the 45 patients exhibited dyskinesia, all of whom had received previous treatment with neuroleptic medications. In the 12 patients without any history of neuroleptic exposure, we detected no cases of dyskinesia.

Although increasing age appears to be associated with greater prevalence of dyskinesia between the second and sixth decades, there is a growing body of evidence that this association does not exist among patients over the age of 60. In addition to the results presented by Dr. Khot and Dr. Wyatt, Smith and Baldessarini (3), in a separate meta-analysis of nine studies, found no significant increase in the prevalence of tardive dyskinesia in patients over age 70 (N=559) compared to those between ages 60 and 70 (N=566). In a prospective study of tardive dyskinesia in the elderly, Saltz et al. (4) reported that "age did not have any significant effect on the prevalence of tardive dyskinesia within the age spectrum of 57 to 96." Similarly, in our study the mean±SD age of the patients who exhibited dyskinesia did not differ significantly from that of the patients without dyskinesia (73.7±8.9 and 72.1±8.0, respectively; t=0.5, df=43, p=0.60). We concur with Drs. Khot and Wyatt that the risks of developing abnormal movements from neuroleptic medications may be less than previously thought, particularly in the elderly. If tardive dyskinesia results from the supersensitivity of striatal dopamine-mediated synapses, the prevalence of this condition may cease to increase after age 65 because of the reductions in striatal neurons and dopamine content that are concomitants of normal aging (5, 6).

### Control Groups in the Study of Effects of Medication

SIR: In their article "Neuropsychological Performance in Medicated and Unmedicated Patients With Tourette's Disorder," R.A. Bornstein, Ph.D., and Victoria Yang (1) correctly emphasized that medication effects are best elucidated through the study of the same group of patients before and after initiation of treatment, i.e., with patients serving as their own control subjects. Nevertheless, their study of the effects of medication in parallel groups (medicated versus unmedicated) of patients with Tourette's disorder is a methodological advance beyond studies that rely solely on behavioral and cognitive changes elicited by therapeutic agents in normal healthy volunteers.

Implicit in the study of drug effects in normal subjects is the idea that the disorder per se causes no diminution in performance. Decremental performance effects demonstrated in normal subjects are then attributed to drugs required by a population of patients for the treatment of a preexisting disorder. For example, inferences are often drawn about the impact of classical $H_1$ blockers on the driving performance of allergic rhinitis patients on the basis of the impact in normal healthy volunteers of sedating antihistamines on behavioral skills considered important for driving (2). The interpretation of these data from the testing of psychomotor capabilities, which include extended attention span, vigilance, visual tracking, rapid information processing, and reaction time, is not possible when the effects of the disease symptoms per se on cognition and performance are largely unknown (3). What is truly germane is whether or not, to what extent, and in what manner the target disorder has an impact on the sufferer and the subsequent effects that medications have on the performance of the patients, not normal subjects. Unfortunately, because Dr. Bornstein and Ms. Yang were not able to use patients as their own control subjects, they could not definitively address these issues.

Genuine concerns about the potential negative effects of psychotropic medications continue (witness protests against the use of methylphenidate and neuroleptics at APA annual meetings). Our profession remains obligated to obtain a more comprehensive understanding of the impact of medications, but we can only evaluate these effects once we have learned more about the impact of the disorders themselves on performance.

There is an indication in the literature and, I believe, in the minds of practitioners that some medications have beneficial effects on overall performance. The regular use of antiepileptic agents, for example, appears to diminish the relatively increased risk for traffic accidents noted in people with epilepsy (4). The acute use of β blockers has been well-established as an effective treatment for performance anxiety in public speakers and musicians (5). Implicit in this utilization of β blockers is the belief that performance anxiety is a state which adversely affects cognitive and psychomotor performance. The negative effects of β blockers on performance may only pertain to cardiac patients who are normal in terms of concomitant anxiety.

To determine the true effects of drugs on neuropsychological performance and behavior, one must conduct placebo-controlled serial studies in patients while they are symptomatic and asymptomatic, with and without medications. In the case of disorders such as Tourette's disorder, which is usually associated with a lifelong course, the study by Dr. Bornstein and Ms. Yang of parallel patient groups differing only in terms of pharmacotherapy represents a feasible and practical alternative.

## PTSD and Risk of Suicide

Sir: Herbert Hendin, M.D., and Ann Pollinger Haas, Ph.D. (1) reported an informative study of attempted suicide and preoccupation with suicide among a group of military veterans referred to them on the basis of combat experience in Vietnam and suspected posttraumatic stress disorder (PTSD). However, their observation that three of the 100 veterans in the group with confirmed PTSD committed suicide during the study, presented without comparison to an appropriate control group, provides questionable support for the authors' stated conclusion that PTSD poses a considerable risk of suicide. Does the reported frequency of suicide among Vietnam combat veterans with confirmed PTSD surpass or fall short of the frequency that would be observed in a comparison group of Vietnam combat veterans without PTSD, given that the two groups of veterans have similar prevalences of drug and alcohol abuse and other psychiatric or social risk factors for suicide that may coexist with PTSD?

Dr. Hendin and Dr. Haas also reported that numerous studies have shown a consistently higher risk of suicide among Vietnam veterans, ranging from 11% to 65%, than among nonveterans of the same age. However, the upper limit of this range of risk assessments is based on a problematic comparison of the mortality experience of males who were draft-eligible to that of males who were draft-exempt as a result of the military draft lotteries of the years 1970–1972 (2). During the early 1970s, shifts in the composition of the military toward an all-volunteer force, even among ground combat forces, cast doubt on the suitability of draft eligibility as a proxy for service in Vietnam (3). The reported 65% excess of suicides among the draft-eligible males cannot be attributed to Vietnam experience in the absence of information about where, or even whether, these males served in the military.

Although the results of other studies cited by Dr. Hendin and Dr. Haas indicate that Vietnam veterans are at higher risk for suicide than other veterans or nonveterans of similar age, the Vietnam veterans' risk was generally less than 25% higher, a modest difference in terms of epidemiologic risk assessment (4). In the largest study conducted to date, which was not cited by Dr. Hendin and Dr. Haas, Veterans Administration researchers found a 7% lower risk of suicide among Vietnam veterans than among veterans who served elsewhere during the Vietnam era (5).

DANIEL A. POLLOCK, M.D.
*Atlanta, Ga.*

## Dr. Hendin Replies

SIR: Our study enabled us to show that guilt over actions in combat was the most significant factor distinguishing veterans with PTSD who became suicidal from those who did not. We are in no position to confirm or refute epidemiological studies on the overall incidence of suicide among Vietnam veterans. Our mentioning that three of our patients in the suicidal group did kill themselves in the course of the study simply suggested that we were dealing with a population at risk. No conclusions were or could be drawn from that fact.

The weakness in the epidemiological studies cited by Dr. Pollock is that they ignore the observations of most clinicians that those at risk for suicide are not simply Vietnam-era veterans, or those who served in Vietnam, but those who after intensive combat experience developed PTSD. Only an epidemiological study focused on this group can address that question. Our study did not attempt this but, rather, sheds light on which of the Vietnam combat veterans with PTSD are likely to be suicidal and why.

HERBERT HENDIN, M.D.
*New York, N.Y.*

## The Dissociative Experiences Scale

SIR: The Dissociative Experiences Scale has been used as a measure of dissociation in a number of articles published in the *Journal* (1, 2). The questionnaire seems to be becoming a recognized tool in modern psychiatric research. It is worth reviewing the original validation paper by Bernstein and Putnam (3) to see whether this self-report questionnaire merits such faith on the part of its users.

Bernstein and Putnam reported in their 1986 paper that the questionnaire was given to small groups of patients with various diagnoses (for example, posttraumatic stress disorder, multiple personality disorder, phobias, and schizophrenia) and to groups of normal adults and adolescents. In a scatterplot graph included in the paper, one sees that the scatter of scores is very wide in all groups except normal adults. Thus, for example, the scores of the adolescent group overlap with the lower 50% of the scores of the multiple personality disorder group. Although the median values for each of the groups were significantly different statistically, it is obvious that the questionnaire cannot be used, as the authors claimed, "to differentiate between subjects with and subjects without dissociative disorder."

The test-retest reliability was 0.84. This figure has now been cited (5 years later) by Barbara Sanders, Ph.D., and Marina H. Giolas, M.A. (2) to strengthen their conclusions that level of dissociation correlates with degree of childhood trauma in adolescent inpatients. However, the test-retest reliability was measured using only 12 adults and 14 adolescents; I can see no reason to expect that clinical groups will complete the questionnaire with the same reliability, yet this was not tested.

The article by James A. Chu, M.D., and Diana L. Dill, Ed.D. (1), again on the subject of dissociation and childhood trauma, pointed out that "one-quarter of the sample [inpatients] . . . had symptom scores at or above . . . the established median score of patients diagnosed with PTSD." It is worth reminding ourselves that "the established median score" was obtained in the validation study using only 10 Vietnam veterans who were taking part in another study. Is this score "established" because it is valid or because it is 5 years old and people have forgotten how it was arrived at? Based on these creaking foundations, conclusions are now being made about the degree of trauma to which abuse victims have been subjected.

Dr. Chu and Dr. Dill also concluded that dissociative disorders are being underdiagnosed, because they obtained high scores from a group of female inpatients that did not contain a high proportion of dissociative diagnoses. However, nobody seems to be concerned that the Dissociative Experiences Scale might be measuring something other than dissociation. All of the questions in the instrument are scored in the same direction, so that someone who had a tendency to say yes to any question (a distinct possibility with multiple personality disorder) would score high.

A measure of dissociation would be very valuable, but I suggest that more effort is required to validate and refine the Dissociative Experiences Scale before it is added to a growing list of research instruments that researchers unquestioningly accept as reliable and valid.

ANDREW WIENER, M.B., CH.B.
*London, England*

## Drs. Putnam, Chu, and Dill Reply

SIR: The questions raised by Dr. Wiener concerning the validity of the Dissociative Experiences Scale are based on a very narrow reading of the literature available on this instrument. The scale has been used in over 20 scientific studies published in refereed journals, including six studies in this journal. Three studies (1–3), specifically conducted as replication studies, reported results very similar to those of the original validation study, and several other studies reported replication of the findings of the original study as applied to specific diagnostic groups. Dr. Wiener expresses concern that the median PTSD score used by Drs. Chu and Dill was based on data from only 10 Vietnam veterans. Currently, there are one published study and two studies in press, involving in excess of 100 combat veterans, that replicate the original findings. The Dissociative Experiences Scale was also included in the National Vietnam Veterans Readjustment Study, and data on its predictive validity for PTSD have been presented at national scientific meetings.

The test-retest statistic criticized by Dr. Wiener has been replicated by us on several occasions; e.g., our test-related Spearman correlation at 1 year is 0.78 in a sample of 83 mothers participating in an ongoing study of sexually abused children. Dr. Wiener's concerns about the relatively high scores of adolescents reflects lack of awareness of the developmental roots of dissociation. Dissociative Experiences Scale studies that have looked at this issue find a significant negative correlation of scale scores with age. This pattern is also true for studies of hypnotizability, a strong correlate of clinical dissociation, and for studies of the frequency of depersonalization symptoms in adolescents and adults. Children and adolescents are normatively more dissociative than adults, and their scores on the Dissociative Experiences Scale reflect this.

Bernstein and Putnam have never claimed that the Dissociative Experiences Scale is a diagnostic instrument and specifically cautioned against this use in the original validation article. However, the instrument does have very good discriminant validity for dissociative disorder diagnoses. For example, a recent multicenter study of 1,340 subjects found that the Dissociative Experiences Scale blindly categorized patients correctly into dissociative disorder and nondissociative disorder groups 85.5% of the time. This is an excellent performance for a simple 28-item, self-report questionnaire.

In summary, the Dissociative Experiences Scale has proven extremely useful for screening psychiatric populations for dissociative patients, for quantifying the contribution of dissociation to behaviors such as self-mutilation and suicidality and disorders such as PTSD, for investigating potential neurobiological mechanisms of dissociation, and for the epidemiological study of dissociation. The validity of the scale rests not on "creaking foundations" but, rather, on an increasingly broad international base of clinical investigation that spans many scientific disciplines. In our efforts to support researchers and clinicians interested in dissociation, we will continue to investigate the psychometric properties of the Dissociative Experiences Scale, to offer periodically updated information on it, and to consult with researchers using this instrument. French, Spanish, Dutch, and Cambodian language versions are available on request.

The limitation on references in letters to the Editor precludes complete documentation of the points we have made. We will gladly send any interested reader a fully referenced version of this letter.

## Dr. Sanders Replies

SIR: In responding to the issues raised by Dr. Wiener, our own research with the Dissociative Experiences Scale provides considerable reassurance concerning its reliability and also some degree of assurance regarding its validity. The findings cited here were presented in two separate papers (Pitblado and Sanders, 1991; Giolas and Sanders, 1991) at the 8th International Conference on Multiple Personality/Dissociative States in Chicago in November 1991. The following is a summary of these studies.

In the research conducted by Colin Pitblado, Ph.D., and myself, 46 undergraduate students at the University of Connecticut were given the Dissociative Experiences Scale on two occasions 6–8 weeks apart. Their scores on the two occasions had a correlation of 0.79. Odd- and even-numbered items from the first administration of the scale were scored separately to permit calculation of a split-half reliability coefficient for the same subjects. The resulting coefficient was 0.93. The corresponding coefficient from the second administration was 0.97. To assess the effect of a longer time between administrations, odd-numbered and even-numbered item versions of the Dissociative Experiences Scale were prepared and presented to 16 undergraduates at Teikyo Post University. These students were given one version of the scale near the beginning of a semester and the other at the end of the semester, approximately 11 weeks later. The correlation between these sets of scores was 0.90, indicating substantial stability for performance, controlled for familiarity with individual items.

The validity issue was addressed by Marina Giolas, M.A., and myself in an experimental investigation of the experience of pain in high- and low-dissociating female college students. Forty-eight women who scored above 20 on the Dissociative Experiences Scale were selected for the high-dissociation group, and 48 who scored below 20 constituted the low-dissociation group. High dissociators showed a significantly greater tolerance for ischemic pain than did low dissociators. Moreover, across both groups, Dissociative Experiences Scale scores were correlated significantly, albeit modestly, with within-subject differences in ratings of sensory pain and ratings of emotional suffering associated with the pain. In other words, women with higher scores on the Dissociative Experiences Scale tended to be less bothered by sensory pain than women with lower scores. These results constitute the first experimental validation of the Dissociative Experiences Scale in which a behavioral criterion of dissociation was used.

In addition to our own findings, two large-scale studies that replicated and extended Bernstein and Putnam's 1986 results have been published by other investigators (1, 2). Clearly, additional psychometric research with the Dissociative Experiences Scale is needed; however, the results obtained so far indicate that the newly developed scale is a useful measure of dissociation in both clinical and nonclinical populations.

## Failure to Use ECT in Treatment of Catatonia

SIR: The case report by Jeffrey D. DeLisle, M.D., "Catatonia Unexpectedly Reversed by Midazolam" (1), raised a number of clinical concerns. Over the years numerous treatments have been used in the treatment of catatonia, including thiopental sodium interviews, intravenous amobarbital, intravenous lorazepam, neuroleptics, bromocriptine, dantrolene, and ECT. The brief clinical vignette failed to mention the unique role that ECT plays in the reversal of catatonia of any origin. The APA task force report of 1990 (2) endorsed ECT as an effective treatment for the catatonic subtype of schizophrenia. In addition, case reports of organic catatonia (3) as well as lethal catatonia (4) indicate a common therapeutic pathway in the reversal of this potentially lethal state.

The omission of discussion of ECT in this case report is of concern. Practitioners should be advised to pursue treatment of catatonic patients with ECT, as the psychopharmacologic options appear quite limited.

STEPHEN J. MASIAR, M.D.
*West Brentwood, N.Y.*

SIR: Dr. DeLisle described a case of catatonia in which midazolam elicited transient relief. He failed to discuss the inadequate treatment of this patient, possibly because *DSM-III* restricts treatment options.

Catatonia developed in a patient suffering from schizophrenia when she discontinued her medication. She required gastric intubation, and when she was given midazolam for anesthesia, she "began conversing loquaciously in an appropriate though tangential and delusional vein." She was repeatedly given midazolam and loxapine, so that "her catatonia improved, but her psychotic symptoms did not. A week later she began refusing all medication, suffered a partial catatonic relapse and worsening of psychosis, and went on to a prolonged course of illness." The report is presented as an example of the resolution of catatonia with midazolam when lorazepam had not been successful. In this description, the author encouraged the belief that benzodiazepines are useful agents in resolving catatonia, a belief that is poorly founded in the literature.

What is missing in this story is the effective treatment of the patient. Catatonia is remarkably responsive to ECT. Did the author fail to use ECT because the diagnosis was schizophrenia, a condition that is erroneously acknowledged as unresponsive to ECT? If so, the case is another example of the tragic consequences of the rigid classification inherent in *DSM-III.*

ECT has been described as effective for catatonia, in any of its expressions and forms, since the first cases of Meduna in 1934 and Cerletti in 1938. While *DSM-III* acknowledges catatonia only as a modifier of schizophrenia (diagnosis 295.2x), the literature is filled with extensive examples of catatonia appearing in patients with mania, depression, infections, endocrinopathy, and neurotoxic syndromes, as well as schizophrenia, and being responsive in each syndrome to ECT.

A colleague and I (1) recently argued that catatonia should be considered a separate class, distinct from schizophrenia, in *DSM-IV.* Such a reclassification would have encouraged the physicians treating this patient to introduce ECT at the earliest opportunity, allowing the patient to recover from the acute relapse.

MAX FINK, M.D.
*St. James, N.Y.*

## Dr. DeLisle Replies

SIR: I am grateful to Dr. Masiar and Dr. Fink for the opportunity to expand my thoughts on this complicated case. Several factors made the use of ECT in Ms. A's case impossible. First, the patient was both incompetent to give informed consent and refusing treatment. Second, she was being treated in a psychiatric unit in a remote and rural area that lacked the necessary medical amenities such as cardiac and oxygen monitors and anesthesiologists. Court-authorized transfer to another facility would have consumed time, and the accepting facility had at least temporarily refused her admission because of the gastrointestinal bleeding. By the time preparations for ECT could have been made, the patient was no longer catatonic, and the indication for ECT had passed. This example highlights the fact that many psychiatrists and their patients, especially in rural areas, lack access to this potentially life-saving treatment.

I heartily concur with Dr. Masiar and Dr. Fink that catatonia is poorly treated by the usual methods used for schizophrenia. While I do not dispute that ECT is an effective treatment for catatonia, I take exception to Dr. Fink's assertion that "the belief that benzodiazepines are useful agents in resolving catatonia . . . is poorly founded in the literature." In Ms. A's case the catatonia had resolved with midazolam and later with high doses of lorazepam; her partial relapse occurred only after she began refusing medication. The many case reports and small series reported in the literature, including the ones I cited, show that dramatic clinical improvements have occurred in many different patients given parenteral or high oral doses of benzodiazepines.

It is also noteworthy that intravenous barbiturates have successfully reversed catatonia, albeit temporarily (1, 2). Given the role of intravenous barbiturates in ECT induction, it is reasonable to query whether the clinical success of ECT in catatonia is due to the induction or the convulsion and, in any case, whether there is a shared mechanism of action. A 1953 study comparing catatonic patients who received ECT, thiopental sodium, or both showed equal improvements in all groups (2). More recent studies of sham ECT versus actual treatment demonstrate the clear superiority of the latter in depressed patients, but these results do not necessarily apply to catatonia, which has never been studied with sham ECT. As Sackeim remarked in a review of the subject, "There are no grounds as yet to determine whether the mode of action of ECT is the same or different in the various conditions for which it is effective" (3).

Even though these unanswered questions about ECT should give its proponents pause, with our current state of knowledge, ECT seems to be the most reliable treatment for catatonia. Still, the empirical successes achieved by benzodiazepines warrant serious attention and, in the face of failure or unavailability of other options, deserve a place in the therapeutic armamentarium. If more rigorous studies prove that benzodiazepines are efficacious in some catatonic patients, this treatment would have the advantages of rapidity and ease of administration, decreased risk from anesthesia, possibly fewer cognitive side effects, and greater acceptance by patients.

## Autism Syndrome as a Final Common Pathway of Behavioral Expression for Many Organic Disorders

SIR: The article "The UCLA-University of Utah Epidemiologic Survey of Autism: The Etiologic Role of Rare Diseases" by Edward R. Ritvo, M.D., and associates (1) helps to reestablish a path of progress toward understanding autistic behaviors. The verification of the coexistence of autism and organic CNS disorders is a very important finding; however, the implication that this is a new or novel finding is misleading, as many historical works have pointed to this conclusion. Work done at the University of Utah from 1965 to 1978 clearly demonstrated the presence of organically based learning defects in autism (2), and our 1976 study of reports of neuropathology in childhood psychosis and autism clearly documented an extensive literature indicating various CNS pathologies in these disorders (3).

The field of research into childhood psychoses has been in scientific disarray for over 100 years due to a binary thinking process in which an organic disease condition and a childhood psychosis or autism syndrome are seen as mutually exclusive. The basic polemic has been that these aberrant behavioral syndromes are either organic diseases or they are psychosis, autism, dementia infantalis, etc. The truth is that organic disturbance and autistic syndromes of behavior go hand in glove with each other, and they are mutually *in*clusive, not mutually exclusive. We believe that an error in diagnostic conceptualization has occurred, because historically the presence of CNS pathology has been used to *exclude* the diagnosis of a childhood psychosis or autism.

Kraepelin (1896) based his system of nosology on the assumption of no known external organic causes, and this criterion of exclusion strongly influenced de Sanctis (1905) and Heller (1908) in their pioneer efforts to delineate childhood psychosis syndromes. It is notable that both of these authors specified "no neurological abnormality" (in parallel with Kraepelin) as part of their diagnostic criteria. Thus, the binary concept of mutual exclusivity between childhood psychosis and organic disease had been drawn.

This polemic tension existed in the mind of Sancte de Sanctis himself, and his writings reveal that on separate occasions he would oscillate between inclusion and exclusion of a case, depending on the coexistence of a known organic disorder. In some of his writings he wondered whether his "dementia praecocissima" could spring from the substrate of certain mental retardation or encephalitis cases. Nosology wars between dementia praecocissima (1905) and Heller's syndrome (1908) raged in Europe until 1958, when C. de Sanctis and G. Bollet attempted to document finally the nature of these syndromes and the assignation of the proper historical credits to each school (4).

Meanwhile, in America and Europe, Heller's syndrome was being written out of existence because of the discovery in neuropathological studies that the majority of these cases were due to conditions such as cerebral lipidoses, tuberous sclerosis, encephalitis, and other abnormal findings. In similar fashion, dementia praecocissima was abandoned as Cappon (1953) declared that the syndrome was related to a "heterogeneous ensemble of organic defects" such as Tay-Sachs disease, aphasias, etc. In America, Kanner (1943) started a replay of the European cycle with the concept of autism as a separate entity "without regression and evidence of organic defect."

In conclusion, we believe the literature clearly supports that 1) autistic behaviors are a final common pathway of multiple CNS neuropathologies (3), 2) autism and childhood psychosis syndromes are perfectly compatible with concomitant CNS neuropathological diagnoses, and 3) descriptions of behavior cannot be used to define or isolate CNS neuropathologies.

## Dr. Ritvo and Ms. Ritvo Reply

SIR: We did not imply that the article contained a "new or novel" finding, and we are surprised that Dr. Darby and Dr. Clark made such an inference. Indeed, we began publishing data in 1965 to support the hypothesis that autism is due to brain dysfunction (1). We reviewed the field and presented our ideas in detail in 1968 (2).

We wholeheartedly agree with Dr. Darby and Dr. Clark that our field has been in "scientific disarray" because of "binary thinking." For example, the word "psychoses" has had several distinct meanings. First, it has been used to refer to a group of illnesses, the psychoses (e.g., schizophrenia, manic-depressive disorder). Second, it has been used in a psychodynamic framework to refer to conditions in which reality testing is faulty (e.g., acute stress-induced regressive state). Third, it often is used to imply etiology—either organic or nonorganic, depending on the user's preference.

A different piece of semantic confusion was caused by the use of the term "autism" as both an adjective (by Bleuler and Kanner initially) and a noun (Kanner's later use and *DSM-III*) (3) to refer to a disease. Thus, a matrix exists for multiple uses with different meanings.

We agree with Dr. Darby and Dr. Clark that these confusions should be relegated to the past. The consensus now is that autism is a behaviorally defined syndrome; it can be caused by one or more types of brain pathology that, in turn, can have one or more causes.

## Need for Integrating Environmental and Biological Factors in Psychiatry

Sir: The article by David Reiss, M.D., and associates on genetics and psychiatry (1) was impressive indeed, and I congratulate the *Journal* for highlighting it. The authors documented how the available data show not only the promise in studying a biological etiology for severe mental disorders, as has been claimed, but the promise in pursuing environmental factors as well. The article provided an excellent and concrete example of how the style of thinking the authors corrected, the style predominant at this time, can corrupt the scientific effort being made. Of course, predominant conceptual styles in any era can distort data in a way that has the same impact. We are accustomed to seeing some of the past excesses in deemphasizing less popular domains that were common to another orientation—psychoanalysis—during its dominance.

However, in any period it is difficult to get a perspective on current thinking. The goal, of course, is not the dead end of being "anti" any legitimate domain—not antibiological, antipsychological, or antisocial—but of psychiatry's becoming a field that truly attempts to attend to all three areas, an effort that is far more difficult than it seems and that continues to elude us. Our tendency, rather, is recurrently to "accept" all three domains, but with a kind of tolerating de-emphasis of the nondominant areas that prevents a truly multidisciplinary effort from being achieved. The report by Dr. Reiss and associates took a major step in redressing this error, an error that constantly threatens to rob our field of one of its most exciting and challenging potentialities: the possibility of bringing together the various domains to provide a total picture.

To the effort being made by the authors, three further steps might well be added. The first step is to undo another tendency that has grown in recent years, the tendency to amalgamate the psychological sciences and the social sciences in one mass, as reflected in the word "psychosocial." This amalgamation does with those fields what we have done in the past with biology: it reduces them in importance and undervalues their complexity.

The second step is to suggest that beyond the "partnership" the authors recommend, the biological, psychological, and social sciences might even better aspire to some sort of integration of findings and synthesis of theory. Not only does each domain need to be respected and developed, but the nature of their interaction needs to be clarified—truly an exciting challenge, which, in fact, Dr. Reiss and his colleagues have begun.

Finally it will also be important to notice the impact of our current style of thinking not only on research and treatment but also on education. By de-emphasizing the psychological and social aspects of the triad, we have driven many with training in those disciplines from focusing on mental disorders and discouraged many college students with interest in those areas from going into medicine and psychiatry.

The report by Dr. Reiss and associates is a gift to our field. I hope we will learn from it and see many more that drive this effort even further.

## Comorbidity of Attention Deficit Hyperactivity Disorder and Other Disorders

Sir: In the lengthy review article "Cormorbidity of Attention Deficit Hyperactivity Disorder With Conduct, Depressive, Anxiety, and Other Disorders" by Joseph Biederman, M.D., and associates (1), only by one word in the Conclusions section is attention deficit disorder in adults mentioned. At the very least, this article by pediatric psychiatrists should have had the words "in children" in the title.

Even if attention deficit disorder is recognized in *DSM-III* only as "residual" in adults, lack of mention in this article was a serious omission. Adult attention deficit disorder was discussed at length in a 1979 book (2) as well as lately in the pages of this journal (3). Attention deficit disorder in adults is a regrettable affliction that, among other things, coexists with the aftereffects of attention deficit disorder in childhood, such as low self-esteem and social fears.

The symptoms in adults are often identical to those in children. Instead of troubles in school, the adults have troubles on the job. Instead of being awkward in the gym, they drop things, bump into them, and get lost while driving. Since imipramine helps enough to enable them eventually to have remedial training (guided by neuropsychological testing) and psychotherapy to repair the self-image, it is essential that the condition be better known. The symptoms described in the article by Dr. Biederman and associates are not merely coexistent; many of them are caused by attention deficit disorder, as the therapeutic test demonstrates. Furthermore, people suffering from severe attention deficit disorder are often misdiagnosed as manic-depressive or schizophrenic, very much to their detriment (4).

LEOPOLD BELLAK, M.D.
*Larchmont, N.Y.*

SIR: The article by Dr. Biederman and associates allows another interpretation of the data. A hereditary triad of overreactivity, lability, and impulsivity, developing in different environments, may present as many diverse clinical pictures. The three traits are common to all, but there may be many different behaviors. All of them— impulsive eating, explosive temper, acting before thinking, inability to stick to plans, overdramatization, etc.—represent impaired self-control. These patients also have depressive symptoms, not because of depressive illness but because being discouraged is an appropriate response to their life situation.

Over 20 years of clinical experience in the psychopharmacotherapy of these conditions has clearly shown that the specific symptoms do not predict drug response, but the basic triad predicts that there is a 90% chance of a positive response to a small dose of one of the antidepressants. The response is immediate. Side effects are rare because of the small doses. There is rapid relapse on discontinuation. A patient's response to antidepressants does not warrant the assumption that one is treating depressive illness. The dose is one-tenth to one-third of the usual dosage for treating depression. Some unknown but different mode of action is involved. There is temporary control, not cure, as with insulin for diabetes.

Research is needed on the difference between amitriptyline and imipramine responders and between trazodone and amoxapine responders. Our preoccupation with specific behavior keeps leading us astray. The National Institute of Mental Health catchment area studies report that 12% of the adult population suffers from these disorders.

*Burlington, Vt.*

SIR: I read with interest the article by Dr. Biederman and associates on comorbidity with attention deficit hyperactivity disorder. I believe that it highlights the importance of identifying comorbid disorders with regard to the clinical treatment of and future research on this common childhood disorder.

In their study, however, the authors may have left out another comorbid disorder. The association of hyperactivity and attentional difficulties in encopretic children was observed by Levine (1). He described children with attention deficit as "task impersistent," seldom finishing anything they start, including defecation. Thus, some of them may have incomplete bowel movements, become gradually constipated, and thereby increase their susceptibility to developing encopresis. Boon and Singh (2) stressed the importance of assessing and treating comorbid disorders such as attention deficit hyperactivity disorder in the successful treatment of encopresis. A review of 30 inpatients with encopresis in the children's psychiatric hospital where I work showed that 11 (37%) had the diagnosis of attention deficit hyperactivity disorder.

FRANKLIN BOON, M.D.
*Richmond, Va.*

SIR: I enjoyed the article on comorbidity of attention deficit hyperactivity disorder with conduct, depressive, anxiety, and other disorders. The article, however, left me with the impression that different types of attention deficit hyperactivity disorder develop differently, mostly because of different brain physiology factors.

I think it is important also to consider that while attention deficit hyperactivity disorder may be present from birth, possible comorbid disorders may develop subsequently because of nonphysiological influences to which the child is exposed, especially including whether the attention deficit hyperactivity disorder is recognized early enough by parents or physicians and is treated or not. It has been my impression over the past 20 years of my clinical child psychiatry practice that if attention deficit hyperactivity disorder is diagnosed and treated early, then there are fewer conduct problems, depressive disorders, anxiety problems, and learning disabilities.

I feel that there are very important clinical applications related to the possibility that attention deficit hyperactivity disorder may be a prime etiological factor in a number of other emotional disorders. There are also very powerful financial aspects, such as the fact that certain insurance companies will not pay for the diagnosis and treatment of attention deficit hyperactivity disorder, whereas they will pay for the diagnosis and treatment of possibly more serious emotional disorders, although more serious emotional disorders could have been prevented had the attention deficit hyperactivity disorder been treated earlier.

As a child and adolescent psychiatrist, I have always been puzzled that there has not been more of a fuss made over the possibility of a connection between one of the most commonly diagnosed child psychiatric disorders, attention deficit hyperactivity disorder, and the most commonly diagnosed adult psychiatric disorders. I very much hope that the article by Dr. Biederman and associates will help contribute to a greater interest in the field of attention deficit hyperactivity disorder and how it is connected to other disorders that psychiatrists are called upon to treat. Perhaps we can even prevent these disorders more easily if we treat attention deficit hyperactivity disorder earlier.

DIRK E. HUTTENBACH, M.D.
*Marietta, Ga.*

SIR: In their review of the comorbidity of attention deficit hyperactivity disorder with other disorders, Dr. Biederman and associates did not mention the high incidence of attention deficit hyperactivity disorder often reported in children with type I neurofibromatosis (1). An adult with type I neurofibromatosis and residual attention deficit disorder was recently treated at our medical center, reinforcing the importance of being aware of comorbidity factors for attention deficit hyperactivity disorder in adults.

Mr. A, a 25-year-old man, presented during his first week of basic military training with severe anxiety and suicidal ideation. After arriving at the training base, he had disturbing memories and dreams about a family member's death from a medical illness and also experienced four transient visual hallucinations of the deceased family member.

Mr. A had been given methylphenidate at age 6 for "hyperactivity." This medication was stopped at age 12, when his symptoms resolved. His family history included a seizure disorder in his father. His work history was striking; he had lost nearly 20 different jobs since graduating with fair grades from high school.

After admission, Mr. A's mood improved, and no further hallucinations occurred. His affect, however, seemed blunted for nearly a week after his initial presentation. Physical examination on admission had revealed numerous café au lait spots on his trunk and proximal extremities (which the patient said were "birthmarks"), axillary freckling, and a single small "buttonhole" lesion on his lower back. Dermatology consultation confirmed our diagnosis of type I neurofibromatosis through several tissue biopsies. Neuropsychological testing was obtained to evaluate for cognitive deficits secondary to the diagnosed disorder, and the results were consistent with mild residual attention deficit disorder.

Subsequent collateral history from Mr. A's mother revealed that his estranged father's seizure disorder resulted from an intracranial mass secondary to type I neurofiromatosis. Prior to Mr. A's discharge, he was educated about the implications of residual attention deficit disorder for job training and performance and was given genetic counseling regarding type I neurofibromatosis. Follow-up for treatment of his attention deficit disorder and for surveillance of the neurofibromatosis was arranged.

The patient's visual hallucinations, blunted affect, and chaotic, unstable job history required us to consider the possibility of prodromal schizophrenia. Transient visual images of a deceased loved one are not uncommon in nonpsychotic individuals undergoing severe stress, and Mr. A's blunted affect was not unlike that frequently encountered in basic trainees with severe adjustment disorders. His poor employment history, however, could not be explained by low intelligence or a personality disorder. A careful physical examination and medical evaluation helped explain this history with the more benign diagnosis of residual attention deficit disorder.

Residual attention deficit disorder in adults whose more striking hyperactivity symptoms resolved in childhood is increasingly recognized as a source of impairment and can be mistaken for thought or personality disorders (2). Heightened awareness of diseases such as type I neurofibromatosis that are comorbid with attention deficit hyperactivity disorder can help lead to appropriate diagnosis and intervention for adults as well as children.

### Dr. Biederman and Dr. Newcorn Reply

SIR: Dr. Bellak raises the issue that our review of the literature was limited to reports on children. Since most of the available literature on this topic is limited to findings in children, our review took such a focus. We could not agree more with Dr. Bellak about the persistence, in many cases, of the syndromatic picture of attention deficit hyperactivity disorder into adulthood, and it is our belief that these comorbidities are likely to be found in studies of adults if such studies are undertaken.

Dr. Huessy proposes another interpretation of the findings reported in our literature review. While we do not agree with his hypothesis, we certainly welcome other points of view. For these points of view to be meaningful, they would also need to be subject to the same rigor as that used to back up the assertions presented in our review.

Dr. Boon raises the interesting notion of comorbidity between attention deficit hyperactivity disorder and encopresis. While we recognize that the former can coexist with a wide array of psychiatric, medical, and developmental disorders, our review was limited to those conditions about which a body of literature was available.

JOSEPH BIEDERMAN, M.D.  
JEFFREY NEWCORN, M.D.  
*Boston, Mass.*

### Response of Obsessive-Compulsive Disorder and Trichotillomania to Serotonin Reuptake Blockers

SIR: Case reports (1, 2), and one double-blind study (3) have suggested an association or linkage between trichotillomania and obsessive-compulsive disorder on the basis of positive responses of both disorders to serotonergic reuptake inhibitors such as fluoxetine and clomipramine. Swedo et al. (3) reported that 12 of 13 subjects responded to clomipramine in one study. We report the case of a 13-year-old girl with both obsessive-compulsive disorder and trichotillomania whose obsessive and compulsive symptoms responded to fluoxetine and to clomipramine, but whose trichotillomania responded minimally to each.

Anna, a 13-year-old girl, presented with a 3-year history of hair pulling (4–6 hours a day) and obsessive-compulsive symptoms (more than 5 hours a day of tapping, counting, and death images and a past episode of compulsive hand washing). Family circumstances included the father's past alcoholism, the mother's past bulimia, trichotillomania, and mild obsessive-compulsive symptoms, and other family history of depression, trichotillomania, and suicide. The patient's early developmental history included occasional extreme tantrums. She was sociable and academically average, but by the age of 10 she was seen as immature and anxious and was pulling out her hair, leaving bare patches and excoriations. Intermittent psychotherapy, one psychiatric admission, and brief treatment with fluoxetine did not alter the picture.

In the hospital Anna was started in an open treatment study of obsessive-compulsive disorder in which she took fluoxetine. The dose was increased over 2 months to 80 mg/day, which she continued to take for 3 months, with a gradual decrease in symptoms until she had no compulsions and 1 hour per day, or less, of obsessions, but there was no change in her hair pulling. Because of the latter, fluoxetine was tapered and clomipramine was begun and increased to 225 mg/day, with continued overall improvement in obsessive-compulsive symptoms over 12 weeks, but little change in her trichotillomania. After 14 weeks of clomipramine treatment, including 4 weeks at 200 mg/day or more, she began behavioral therapy specifically for the trichotillomania. After 8 months of clomipramine, 200 mg/day, Anna had marked improvement in her obsessive-compulsive disorder but no change in her hair pulling.

Trichotillomania has been seen as a compulsion, with increased tension prior to the act of hair pulling and a subsequent sense of release or gratification. Compulsions of obsessive-compulsive disorder are also associated with tension reduction, but not gratification. For this patient, there appeared to be an ego-syntonic, sensual, and kinesthetic quality in the experience of hair pulling that is not described for compulsions in obsessive-compulsive disorder. Not wishing to relinquish her hair pulling, she never benefited from behavioral therapy. Another distinction between obsessive-compulsive disorder and trichotillomania may be the person's awareness of the compulsive act, since the sufferer is painfully aware of the compulsion in obsessive-compulsive disorder, whereas the hair puller often describes an "absence," or dissociated state—something Anna often reported.

In conclusion, this case raises questions about whether obsessive-compulsive disorder and trichotillomania differ in process, function, and response and whether trichotillomanic compulsions can also be subtyped on these dimensions.

# Update on the Dementia Spectrum of Depression

V. Olga Emery, Ph.D., and Thomas E. Oxman, M.D.

*Objective: The primary focus of this review is to examine the usual dichotomy between depressive dementia as functional and reversible and degenerative dementia as organic and irreversible. Method: The authors propose viewing depression, cognitive impairment, and degenerative dementia as intersecting continua. They define five prototypical groups along these continua: 1) major depression without depressive dementia, 2) depressive dementia, 3) degenerative dementia without depression, 4) depression of degenerative dementia, and 5) independent co-occurrence of degenerative dementia and depression. Clinical, neuropsychological, and neurobiological studies comparing these groupings were identified by a computerized literature search covering the past 20 years. References were selected for review if they compared at least two groups. Degenerative dementia was limited to the Alzheimer type. Results: No studies clearly included all five of the prototypical groups. There are methodological problems with each type of research reviewed, but the consensus of the research is that severe cognitive impairment of depression is associated with a variety of organic abnormalities. Depending on the length of follow-up, depressive dementia may not be as reversible as previously thought. Conclusions: The continuum viewpoint encourages longitudinal clinical follow-up for early detection and alleviation of incipient depressive and dementing symptoms. Hypotheses of overlapping pathophysiological mechanisms rather than differential diagnosis become an important research focus. The authors discuss three different types of relationships for future research: 1) interactions, 2) consequences of disease or treatment, and 3) necessary but not sufficient pathophysiology.*

(Am J Psychiatry 1992; 149:305–317)

Disorders of mood are usually associated with cognitive impairment that can range from mild to severe. Mild cognitive impairment accompanying major depression raises little diagnostic or therapeutic uncertainty. When cognitive impairment dominates the clinical picture in patients with symptoms of major depressive disorder, issues arise that necessitate a framework for understanding and classifying these combined disturbances of mood and cognition. The major issue of concern is if and how depressive illness itself causes the severe impairment (i.e., depressive dementia) or if some form of degenerative brain disorder is present. Depressive dementia comprises a subgroup of a broader clinical phenotype called pseudodementia. Previous discussions of pseudodementia (1–3) have illustrated the importance of depressive dementia and tended to dichotomize it on the basis of irreversibility versus reversibility, structural versus functional, or organic versus nonorganic etiology. Questioning these dichotomies, we examined the relationship between depression and dementia from a historical perspective and developed a

---

Copyright © 1992 American Psychiatric Association.

framework using continua to conceptualize illnesses where mood and cognitive disturbances coexist. Using available evidence from relevant clinical, neuropsychological, and neurobiological studies, we then evaluated the dichotomous versus continuous views of disorders of mood and cognitive impairment.

## HISTORICAL BACKGROUND OF THE DICHOTOMY VIEWPOINT

The attempt to differentiate between what have historically been considered "nonreversible" dementing disorders and reversible "dementia-like" disorders has a rich theoretical and clinical tradition. In the mid-nineteenth century, focus on irreversibility as a diagnostic criterion for dementia led to a need for a concept to designate contrasting, "reversible," broad-based cognitive deterioration. The term "vesanic dementia" was used through the 1880s to describe dementing syndromes that appeared reversible (4).

During the late 1800s, "vesanic dementia" was replaced gradually by Wernicke's term "pseudodementia." In 1898, Ganser described three victims of accidents who seemed to "mimic mental weakness" (4). Pseudodementia and the syndrome described by Ganser inaccurately became equated (5, 6). Pseudodementia is better conceptualized as an overarching class, of which Ganser syndrome and depression are only parts (6). Larger series of patients with dementia have revealed that the picture of dementia is approximated by patients with a variety of other neuropsychiatric conditions, including conversion disorder, deafness, delirium, drug effects, epilepsy, hypomania, depersonalization, malingering, normal-pressure hydrocephalus, and schizophrenia (3, 5–9). Although the frequency distribution of disorders approximating dementia remains unclear, what emerges with some clarity is that depressive-spectrum disorders constitute a substantial core in any series of patients with potentially reversible dementia.

Both historical definitions of pseudodementia and current-day case reports center on two characteristics: 1) appearance of organic deterioration of cognitive function and 2) reversibility—remitting of symptoms inconsistent with "true" degenerative dementia (9). In the past few decades, these two characteristics embodied in cross-sectional case series have led to a clinical emphasis on the search for curable presentations of dementia.

## HISTORICAL BACKGROUND OF THE CONTINUITY VIEWPOINT

Both historical and current clinical case series promulgated a dichotomous approach that viewed cognitive impairment as either organic or nonorganic but not both. The dichotomy between organic and nonorganic cognitive dysfunction in depressive disorder was first challenged by Mairet (10) with his conceptualization of "melancholic dementia" as organic. Mairet presented a series of cases of patients with melancholic dementia who showed both organic brain changes and reversibility. He observed that patients with melancholia were found to have changes in the temporal lobe on autopsy. Mairet's melancholic dementia appears essentially similar to depressive dementia as defined today (2, 4, 11, 12).

In 1948 Newton (13) reported that 42% of 76 postmortem brains from patients with affective psychosis demonstrated the neuritic plaques and neurofibrillary tangles associated with Alzheimer's disease. This was greater than the 25% of 24 postmortem brains of patients with schizophrenia that demonstrated plaques and tangles. In 1955 Roth (14) demonstrated that most hospitalized elderly patients with depression, with or without substantial cognitive impairment, did not develop dementia within 3 years. However, Roth et al. (15) also published a seminal paper promoting the use of quantitative assessment of degenerative changes: in a series of 300 autopsies of mental hospital patients, they found that 25% of those regarded as suffering "functional" psychoses showed degenerative changes of moderate or severe degree. Roth et al. concluded that this overlap was due at least in part to the co-occurrence of two disorders.

The association of depressive dementia with subsequent degenerative dementia has also been reported in longitudinal studies (3, 16–18). These studies have emphasized the diagnosis of depressive dementia because the patients responded favorably to antidepressant treatment. However, not all of the patients demonstrated complete or permanent improvement in cognitive impairment after treatment for depression, particularly with long-term follow-up. Bulbena and Berrios (4) reported a positive outcome for only 47% of 61 published case reports. These authors reported a 50% rate of negative outcome in their own series of 22 geriatric patients. Alexopoulos et al. (19) found that 38% of 37 psychiatric inpatients with late-life depression and severe cognitive dysfunction turned out to have degenerative dementia after the depression cleared.

Poor outcome appears to be related to the setting and length of follow-up. For example, Murphy (20) reported that 3% of 124 elderly patients with depression were demented at 1-year follow-up, and Rabins et al. (16) reported that 12% of 17 older depressed patients remained demented at 2-year follow-up. Reding et al. (21) reported that more than 50% of elderly patients diagnosed with depressive pseudodementia at a dementia clinic eventually demonstrated degenerative dementia at 3-year follow-up. Kral and Emery (17) found that 79% of 44 older patients with depressive dementia had developed a dementia syndrome with an Alzheimer phenotype in a 4- to 18-year follow-up.

Although these data suggest rethinking of old paradigms, methodological problems necessitate proceeding with caution. For example, the cross-sectional and longitudinal data cited span several decades. During this period of time there were criterion and definition changes for both affective and primary degenerative dementing disorders. Because of possible selection biases and limited information regarding original and follow-up diagnostic criteria, it is difficult to make comparisons across studies. Therefore, we regard the discussion that follows as heuristic in nature. Future research directions that will lead to greater clarification of the relationship between depressive dementia and degenerative dementia are outlined in the final section of this paper.

## CONTINUA OF DEPRESSION AND DEMENTIA

Consideration of variability in three different processes associated with aging may help to clarify the discrepant historical viewpoints and findings presented here. Although these processes fall along separate continua, we are particularly interested in their co-occurrence or intersection. We therefore describe these three continuous processes and several anchor points for the relevant interaction of these continua to help frame this research review. Each of these processes can be assessed by a variety of continuous measures. Defining a disorder or disease level is not a dichotomous decision. Most of the continuous measures are associated with suggested cutoff points or scores. However, the presence of disease is not as clear as the cutoff points themselves.

For the depressive axis, the separation of depressive symptoms from a depressive disorder is difficult, particularly in the elderly (22). Depressive symptoms are measured by a variety of instruments. Regardless of the instrument and its cutoff score, most community surveys reveal about a 15% prevalence of depressive symptoms in people older than 65 (22). This rate is not different from that found among middle-aged and younger adults. The "gold standard" for depressive disorder is a clinician-based interview. Surveys using this standard for major depressive disorder—the type of depression most likely associated with severe cognitive impairment (9, 12)—reveal rates of 1% to 5%, and the lowest rate is consistently found in subjects older than 65. Of the three age-related continua, this is the only one that is inversely related to age.

For the cognitive impairment axis, cross-sectional studies have shown increases of impairment with age. Longitudinal studies suggest that the degree of and age at impairment are quite variable and specific to the particular cognitive process examined (23). As with measures of depression, neuropsychological test batteries and brief mental status examinations are continuous measures with normal ranges and cutoff scores suggesting impairment. With education, sex, and differences in the form of the test accounted for, substantial declines in cognitive function occur with age, even in the absence of systemic disease (23). Also as with depression, the boundary between age-expected cognitive impairment and early primary degenerative dementia is not easily established (22, 24). Highly age-associated prevalence figures range from 1% at age 65 to 20% at age 86 or older (22, 25). For the degenerative pathology axis, cognitive performance in healthy subjects correlates with structural and functional measures of brain function (23). Age-associated structural changes in normal brains include selective regional neuronal loss, cerebral atrophy, senile plaques, and neurofibrillary tangles (26–28). Functional changes include changes in metabolism and neurotransmitter activity (29). These structural and functional changes vary continuously and are seen in both normal aging and dementia. The demarcation between normal aging and degenerative dementia is not easily defined. Although there are no standards for neuronal loss (28), atrophy (30), or neurotransmitters (29), several groups have suggested age-corrected cutoff scores for number of plaques and tangles necessary for diagnosis of Alzheimer's disease (26, 31).

We now describe five points along the depressive, cognitive impairment, and degenerative pathology axes to define prototypical groups, which, in different combinations, form the subject groups of the research review that follows.

### *Major Depression Without Depressive Dementia*

The first basic group is major depression with minimal or subclinical cognitive deficits. We are reticent to define this group as depression with no cognitive deficits because most research (32, 33) suggests that depression in persons over age 40 nearly always involves some cognitive disadvantage with respect to normal subjects. Poor performance on cognitive examination, allegedly because of poor effort from loss of interest and concentration, is one of the criteria for major depression in *DSM-III-R*.

### *Depressive Dementia*

The second prototypical group is major depression with cognitive deficits that reach clinical proportions, i.e., depressive dementia (3, 6, 12). The primary diagnosis is depression, and cognitive deficits are secondary to depression. As described by Folstein and McHugh (12), this type is an organic but "reversible" cognitive dysfunction, possibly due to factors associated with the pathology of mood disorder, such as brainstem neuronal dysfunction or biogenic amine deficiency. Thus far, it is possible to establish this type only retrospectively, after treatment of depression. In this review we consider the terms "depressive dementia," "depressive pseudodementia," "dementia syndrome of depression" (12), and "major depression with depressive dementia" as synonyms.

Age at first onset of depression is a potentially important characteristic often associated with family history, depressive delusions, treatment response, and cognitive decline. Some studies (34–36) have suggested that late-onset depression in older persons is associated with more medical and neuroanatomical changes and, therefore, greater risk of cognitive impairment or dementia. The evidence remains controversial, however, as to whether late-onset depression is associated with cognitive impairment greater than or equal to that of early-onset depression (37–39).

### *Degenerative Dementia Without Depression*

The third group is primary degenerative dementia (38) without depression. Reported frequencies of primary degenerative dementia without affective symptoms of any kind vary a great deal across studies, ranging from 50% to 100% (14, 40–42). This spread between rates is to a large extent a function of varying criteria for affective symptoms and other methodological variations, such as sample definition and sample selection.

The age at onset of degenerative dementia of the Alzheimer type, like the age at onset of major depression, is a potentially important characteristic often associated with neurobiological and clinical findings (43, 44). As with age at onset of depression, the evidence remains controversial, but results of comparisons of these prototypical groups may be influenced by age at onset.

### *Depression of Degenerative Dementia*

The fourth major point of reference on the axes is the presence of a dementing disorder with different degrees of depression. At issue is whether degenerative diseases of the brain, such as Alzheimer's disease, cause depressive illness or, rather, result in the kind of demoralization that can occur with any major illness. In most cases of this basic type, the primary diagnosis is dementia and depression is secondary. Criteria for a major depressive disorder are more difficult to establish for this type. *DSM-III-R* recognizes this difficulty by allowing for subcategorization of primary degenerative dementia with depressive features; a second axis I diagnosis is not required. Prevalence rates of depression in primary degenerative dementia range from 0% to 50% (40–42). As stated before, such a spread between reported prevalences is due mainly to variations in criteria for depression and other methodological differences.

A variant of this prototype is the dependence of both dementing disorder and depression on a common underlying neuropathology. Dementia may not have preceded the depression temporally. Examples of this type of dual presentation include vascular dementia, Parkinson's disease, Huntington's disease, multiple sclerosis, HIV infection, and normal-pressure hydrocephalus. In cases where the symptoms meet *DSM-III-R* criteria for both dementia and mood disorders, multiple axis I diagnoses may be given.

### *Independent Co-Occurrence of Degenerative Dementia and Depression*

The fifth group of the typology involves co-occurrence of a degenerative dementing disorder and an independent, usually preexisting, recurrent depressive disorder. This type represents a confound for causal explanations of dependency between degenerative dementia and depression. We will address this issue in the course of presenting and interpreting relevant studies as part of the research review.

## REVIEW OF THE RESEARCH LITERATURE

To review published studies on the relationships of these five prototypes of varying degrees of affective and dementing disorders, we performed a computerized literature search covering the past 20 years. We examined the references listed in any articles and book chapters relevant to these relationships. No studies clearly included all five of the prototypical groups. Usually one or two groups were compared with a normal control group and/or with each other. References were selected for review if they compared at least two groups. The scope of this paper does not permit equal attention to all forms of degenerative dementia. Each form has its special issues, all of which cannot be dealt with in a single paper. Therefore, the main focus of this update is on the spectrum of depression and primary degenerative dementia of the Alzheimer type. Age at onset of both depression and degenerative dementia is important but difficult to determine. When studies provided this information, we noted it. For dementia, the best comparison with depression would be with mild rather than severe dementia. We also noted severity when specified.

### *Research on Clinical Features*

*Onset of illness.* A key variable of clinical history is onset of illness. Disease onset in primary degenerative dementia is insidious by definition (*DSM-III-R*). In a study of 124 patients, Zubenko (45) supported this definition by finding that an insidious course was the most common presentation of primary dementia regardless of etiology. Although Zubenko found that the onset of illness in 82% of patients with uncomplicated primary degenerative dementia was insidious, another 14% evidenced uncertain progression.

When depressive dementia is compared with primary degenerative dementia, the time elapsed between onset and seeking medical help is usually shorter (3, 9, 46). For example, Rabins et al. (16) reported a median duration of 2 months of symptoms for 18 subjects with depressive dementia compared with a median of 5 years for subjects with degenerative dementia. Reynolds et al. (47) also found a shorter median duration of cognitive impairment in patients with depressive dementia than in patients with primary degenerative dementia.

The overlap of symptom onset between depressive dementia and primary degenerative dementia is large. In the study of Rabins et al. (16), for example, the range of symptom duration in depressive dementia was 1 week to 6 years and the range in degenerative dementia was 5 months to 7 years. Onset and insidious development do not appear to be pathognomonic for either depressive or primary degenerative dementia.

*History of psychiatric disorder.* Another frequently described feature of the clinical history is previous personal or family psychiatric disorder. A history of previous affective disorder is reported more frequently in depressive dementia than in primary degenerative dementia (3, 16, 46). In an examination of psychiatric history, Rabins et al. (16) found a significantly higher frequency of previous depression in depressive dementia than in primary degenerative dementia—61% versus 6%. The frequencies of a family history of affective disorder in the two diagnostic groups were not significantly different.

In looking only at groups at one end of the spectrum—i.e., the difference between degenerative dementia with and without depressive disorder—Pearlson et al. (48) found an association between family history of affective disorder and depression. They found that 41 patients with primary degenerative dementia in their first episode of depression had significantly more first-degree and second-degree relatives who were depressed than did 71 nondepressed patients with primary degenerative dementia. Pearlson et al. suggested that depression in primary degenerative dementia is genetically related to primary affective disorder.

*Intrapsychic depressive symptoms.* Not surprisingly, in comparing depressive dementia with primary degenerative dementia, investigators such as Rabins et al. (16) reported that depressive dementia involved a higher frequency of current depressed mood and delusions. Similarly, Lazarus et al. (40) noted that patients with depressive dementia had higher scores on items assessing intrapsychic symptoms of depression such as helplessness, hopelessness, and worthlessness. Reynolds et al. (49) also reported that patients with depressive dementia had higher Hamilton Rating Scale for Depression scores for anxiety and loss of libido.

*Cognitive and vegetative depressive symptoms.* The "I don't know" answer is often associated with pseudodementia, as described by Wells (3), and the "near miss" answer, *vorbeireden,* is associated with primary degenerative dementia (50). This distinction has been questioned by Hendricks (51), who found that a "guessing response style" was used significantly more often by patients with primary degenerative dementia than was the "near miss" answer. Young et al. (50) and Emery (6) found that the "don't know" response was used frequently not only by patients with major depression but also by patients with primary degenerative dementia. Emery (6) noted that the "near-miss" answer depends on correct processing of a question; Alzheimer's disease appears to erode the capability for correct processing of questions.

A related clinical feature is behavioral consistency. When primary degenerative dementia is compared with major depression (52) or depressive dementia (3), behavior in degenerative dementia appears more consistent with apparent severity of cognitive dysfunction. For example, the patient with depressive dementia can find his or her way around a hospital when hungry or looking for a television set, but the patient with primary degenerative dementia cannot, irrespective of motivation. This behavioral measure has been empirically supported by Reynolds et al. (47), who found that patients with primary degenerative dementia had significantly more impairment finding their way when indoors or on familiar streets than patients with depressive dementia. Interestingly, Kahn et al. (52) reported that patients with concurrent degenerative dementia and depression had more memory complaints than patients with degenerative dementia without depression, even though their memory testing was better.

Perhaps most important with respect to complaints of memory is the finding by O'Connor et al. (53) that although depressed patients older than age 75 had the most memory complaints, more than half of community residents older than 75 with mild or moderate dementia also complained of memory problems, as did one-third of normal subjects. These results suggest that an older person's complaint of the presence of memory loss has limited diagnostic value.

Finally, sleep disturbance is an important vegetative symptom of major depression. As primary degenerative dementia progresses there is also a breakdown of the sleep-wakefulness cycle, as indicated by nocturnal wandering and daytime sleepiness (48, 54). However, Reynolds et al. (47) reported that patients with depressive dementia differ from those with primary degenerative dementia by having more severe early morning awakening.

### *Research on Neuropsychological Features*

There is a fairly large literature related to the neuropsychology of depression in general but less information relating to the neuropsychology of depressive dementia. A major problem with comparative studies is the lack of attention to the relative severity of dementia. Subjects selected for study of the dementia of Alzheimer's disease usually have a more obvious and severe dementia than subjects selected for study of major depression. Nevertheless, in studies of cognitive function that compare depressive dementia with both primary degenerative dementia and major depression, the most consistent finding is that there are more significant differences between major depression and depressive dementia than between depressive dementia and primary degenerative dementia (6, 12, 55).

*Memory.* Hart et al. (56) compared patients with mild degenerative dementia, normal subjects, and patients with major depression without depressive dementia and found that both the depressed and demented patients showed learning impairments but only the demented patients showed a significantly more rapid rate of forgetting after learning. These investigators suggested that memory was impaired in both disorders but that different psychobiological mechanisms were involved.

In a study of memory in age-matched patients with depressive dementia, primary degenerative dementia, and major depression without depressive dementia, Emery (6) found that the greatest deficit for patients with depressive dementia and for patients with primary degenerative dementia was in delayed recall. In comparing these same three types of patients, Speedie et al. (55) also found that patients with depressive dementia performed worse than depressed patients without dementia on tests of free recall, delayed recall, and verbal delayed memory but not on tests of delayed visual memory. All patient groups performed worse than normal subjects in both studies (6, 55).

Although the majority of comparisons have used patients with unipolar depression and degenerative dementia of the Alzheimer type, interesting and important distinctions are being reported regarding two other groups—patients with bipolar affective disorder and patients with subcortical dementias, a subgroup of degenerative dementias (57)—in a variety of different contexts. Dupont et al. (57) found that young patients with a history of bipolar affective disorder had a type of long-term memory deficit similar to that of patients with Huntington's disease.

*Language.* Turning to the higher cortical function of language, we found fewer data on depressive dementia than we did for memory. Speedie et al. (55) found that patients with depressive dementia were indistinguishable from patients with primary degenerative dementia on the number of items correctly named or on the speed of response. Similarly, Emery (6) found that there were no significant differences between age-matched patients with depressive dementia and primary degenerative dementia on language measures of repetition, confrontation naming, auditory word recognition, sequential commands, complex syntax, or reading commands. Depressive dementia and primary degenerative dementia were discriminated by a responsive speech task (e.g., "How many days in a week?") and a sentence completion task (e.g., "Roses are red, violets are what?"). Linguistically, these two tasks are among the simplest (58).

*Abstraction.* To investigate the cognitive domain of abstract reasoning, Cassens et al. (32) administered the Wisconsin Card Sorting Test to several groups of depressed patients. They found that patients with depressive dementia scored significantly lower than depressed patients without depressive dementia. These researchers concluded that the performance of patients with depressive dementia was similar to that of patients with organic dysfunction.

### *Research on Neurobiological Features*

*Neuropathology.* The average aged brain atrophies and weighs about 8% less than the average middle-aged brain. In degenerative dementia, the brain weighs about 20% less than the average normal middle-aged brain (26). Neuritic plaques and neurofibrillary tangles are the hallmark of Alzheimer's disease, but they are not specific to it. In fact, several investigators have reported that after age 80 there is substantial overlap between the brains of patients with degenerative dementia and those of age-matched normal subjects (59). To control for this high rate of overlap of neuropathology with age, the widely used Khachaturian diagnostic criteria for Alzheimer's disease (31) were devised by using an age-adjusted number of senile plaques per square millimeter in sampled microscopic fields.

Thus far, there have been too few autopsy studies of depressive dementia to make any definite conclusions. However, as already noted, some neuropathological studies have suggested an association between severe depression and the pathology of degenerative dementia. This may simply be the co-occurrence of depressive disorder in the context of the higher prevalence of primary degenerative dementia associated with age. However, there have been reports suggesting that degenerative dementia is more likely to occur in patients with depressive disorders than in patients with or without other psychiatric disorders. Brown et al. (60) reported that 62% of 29 patients with affective disorders, compared with 16% of 148 patients with schizophrenia, had primary degenerative dementia or vascular neuropathology. Kral and Emery (17) found that 79% of 44 elderly patients with depressive dementia developed primary degenerative dementia over a long-term follow-up. In nine of these patients studied postmortem, neuropathological examination revealed the typical markers of Alzheimer's disease: neuronal loss, neurofibrillary tangles, and neuritic plaques. Although other longitudinal accounts found smaller percentages of cases of depressive dementia with an ultimate course of primary degenerative dementia, the figures nevertheless appear much higher than the usual 5%–10% prevalence figures for degenerative dementia in the general population over 65 years of age.

A related neuropathological finding is the association of degenerative changes in subcortical nuclei in patients with degenerative dementia who have concurrent major depressive disorder. Zubenko and Moossy (61) and Zweig et al. (62) both reported neuropathological findings indicating the presence of more neurofibrillary tangles in the locus ceruleus, substantia nigra, and central superior raphe nucleus of patients with Alzheimer's disease who also had major depressive disorder than in subjects who did not have major depressive disorder. These findings suggest a subcortical pathological role for some depressive symptoms in Alzheimer's disease.

*Neuroimaging.* There are two basic kinds of neuroimaging methods: those which assess neuroanatomical structure (e.g., computerized tomography [CT] and magnetic resonance imaging [MRI]) and those which assess functional measures of the neural substrate (e.g., positron emission tomography [PET], regional cerebral blood flow [rCBF], and single photon emission scanning [SPECT]).

A substantial body of evidence reveals that CT-estimated tissue density decreases and ventricle size increases with age (30, 63). Some studies suggest that norms for the elderly with optimal health are different from those in subjects with a history of chronic medical diseases (30). It is also important to note that there may be different mechanisms for the occurrence of sulcal atrophy and for ventricular enlargement. Age-related changes in these measures do not correlate very highly.

In comparisons between normal elderly subjects and patients with primary degenerative dementia, a greater degree of generalized atrophy is seen in those with dementia (30, 35, 39). There appears to be a correlation between brain atrophy and severity of dementia, especially when variables such as education and intelligence are controlled for (35, 39, 64). Nevertheless, there exists considerable overlap in atrophy of brain tissue between age-matched normal subjects and persons with dementia (30). There have been attempts to find other CT scan measurements specific for degenerative dementia. To date, however, no CT or MRI neuroradiographic finding is pathognomonic for primary degenerative dementia.

A variety of CT abnormalities suggesting ventricular enlargement or tissue atrophy have also been observed in elderly depressed patients (35, 65). Brain CT and MRI studies have shown differences between late-onset and early-onset depression; late-onset depression has been found to be more comparable to primary degenerative dementia (22, 34–36).

In one of the few neuroimaging studies to specifically examine the dementia of depression, Pearlson et al. (39) compared normal subjects with three prototypical groups all older than 59 years of age. Measures of both ventricle size and CT attenuation (density) showed a consistent pattern of increasing abnormality from normal control subjects through patients with major depression without dementia to those with dementia of depression to those with degenerative dementia without depression. Many but not all of the depressed patients had early-onset depression, not late-onset depression.

Hyperintensities on MRI scans are an additional important but controversial structural finding related to aging, depression, and dementia. Many patients show white matter lesions on MRI scans that are not demonstrated on CT scans. These patients have a significantly greater incidence of cardiovascular risk factors than patients without white matter lesions. These hyperintensities are frequently but not exclusively found in multi-infarct dementia (66, 67). Although neither the differential diagnostic nor conceptual significance of these white matter lesions is understood at present, investigations of depressed patients are providing some intriguing findings. Alexopoulos (34) reported more frequent hyperintensities in depressed patients with onset of illness after 45 years than in patients with an earlier age at onset. Coffey et al. (68), using an MRI hyperintensity scoring system, noted mild periventricle caps or halos in all elderly normal control subjects as well as mild deep white matter hyperintensities in the majority of their normal subjects. In elderly depressed patients referred for ECT, the hyperintensities were more severe and subcortical gray matter nuclei were involved. Rabins et al. (36) reported a similar finding in patients with late-onset depression.

One final note regarding structural neuroimaging relates again to bipolar affective disorder. Along with the intriguing neuropsychological similarities between bipolar disorder and subcortical degenerative dementias, neuroimaging structural similarities between these disorders have been reported. In a large sample of younger patients, Andreasen et al. (69) demonstrated CT ventricular enlargement in patients with bipolar disorder that was independent of age, unlike the association between age and enlargement found in patients with unipolar depression. Similarly, Dupont et al. (57) reported that 47% of 19 young male patients with bipolar disorder demonstrated subcortical MRI hyperintensities involving white matter. None of their control subjects demonstrated these findings, and all seven of their patients with abnormalities who were available for 1-year follow-up still demonstrated the abnormalities. Long-term follow-up of these patients into later life will be most valuable.

At this point, it appears that structural imaging results, rather than discriminating between depression and dementia, point to some overlap if not association between geriatric depression and bipolar depression on the one hand and dementia on the other.

Of the three types of functional neuroimaging, PET has produced more consistent findings than rCBF or SPECT, so we limited our review to this modality (70, 71). In contrast to results from structural imaging, functional imaging with PET appears to suggest more characteristic differences between late-life major depression and primary degenerative dementia. Before discussing these findings, however, it is important to acknowledge some of the methodological problems that may influence clinical interpretations of studies using this complicated technology (72). These limitations include variations in mental activity of the subject during the procedure, the need for adjustment for focal atrophy, difficulties with consistent anatomical localization, and the necessity to adjust significance levels for the large number of statistical comparisons made with small groups of subjects. Given these limitations, primary degenerative dementia appears to have a characteristic pattern of glucose hypometabolism. The primary areas involved are the posterior parietal cortex, often with extension into adjacent temporal and occipital lobes and sparing of the primary sensorimotor cortex (73, 74). This temporoparietal pattern is found in most patients with primary degenerative dementia but not in patients with depression, patients with multi-infarct dementia, or healthy age-matched control subjects (73). However, the pattern has been reported in reversible normal-pressure hydrocephalus (74).

Cerebral metabolism is also altered in depression (75). Buchsbaum et al. (76) found a smaller anteroposterior gradient in glucose metabolism in depressed patients than in control subjects. The order of magnitude of the difference was similar to that between normal subjects and patients with multi-infarct dementia (77). In a series of studies, Baxter et al. (78, 79) found that younger patients with unipolar depression had metabolic asymmetries, most prominent in the posterio-inferior frontal area, which normalized with methylphenidate administration; these patients had a positive response to clinical tricyclic antidepressants. In a subsequent, larger series, Baxter et al. found that patients with unipolar depression had significantly lower metabolic ratios of caudate nucleus to whole hemisphere values than did two other patient groups or control subjects. Overall, these studies suggest a left anterolateral prefrontal cortex abnormality in major depression.

*Neurophysiology.* Concentration and attention are related to cortical arousal. An early measure of cortical arousal was the measurement of the threshold of barbiturate sedation. Both Hemsi et al. (80) and Cawley et al. (81) demonstrated sedation in elderly patients with depression at lower doses of barbiturate. The lower threshold for sedation was comparable to that in degenerative dementia. Electrophysiologic disturbances parallel these findings. For example, Hendrikson et al. (82) demonstrated latency delays in evoked auditory potentials in elderly depressed patients compared with age-matched control subjects. The delay was similar in direction but not as great as that in patients with primary degenerative dementia. The delayed response remained even after clinical improvement in depression. Brenner et al. (83) found that about one-third of waking EEGs from patients with primary degenerative dementia showed moderate to severe abnormalities, that patients with depressive dementia evidence a significantly higher percentage of generalized abnormal EEGs than do normal control subjects, and that patients with depressive pseudodementia show greater slowing of the dominant posterior rhythm than do normal control subjects. Overall, however, there is a large overlap between normal aging, major depression, depressive dementia and mild to moderate degenerative dementia.

More recent neurophysiological research has focused on sleep electroencephalography. The sleep EEG of the elderly person with depression but not dementia has been characterized by a shorter latency to the first REM period, a longer first REM sleep period, a higher percent of REM sleep, and greater density of phasic eye movements than the sleep of patients with primary degenerative dementia. In contrast, the sleep of subjects with degenerative dementia shows progressive loss of phasic eye movements during REM sleep, loss of spindles and K complexes in non-REM sleep, a tendency for the number of delta waves to decrease, and a tendency for slow-wave sleep to decrease (54, 84).
